There is no single point which should so thoroughly engage the attention of the physician as the care of the dejections of the patient. In many instances it is necessary for the physician to inspect the passages from the bowels, and unless you give proper directions regarding the manner in which they should be kept, you will find, much to the annoyance of every one, that they have been quietly slipped into some closet or room immediately adjoining the sick-room, or some other equally unsuitable place. Such safe-keeping, however, hardly comports with a proper degree of cleanliness, and you should, therefore, give special directions, in case it is desirable that the dejections should be preserved until your next visit, that they shall be, if possible, carried out of the house, or at least that they should be carried into some out-room or bath-room in which a window is constantly open.

In addition, you may observe some preliminary precautions, in cases of dysentery, typhoid fever, or where a septic condition is present; in short, all those cases in which you wish to destroy the odor immediately, as well as any organic putrefactive matter which may be present in the dejections by employing some disinfectant.

For this purpose I know of no substance that acts more promptly and efficiently than permanganate of potash.

A solution of the strength of one grain to the ounce of water, is sufficiently strong, and a few ounces of this liquid poured into the vessel that is to receive the

discharges, will correct the most offensive odor in a very short time.

You will recollect that permanganate of potash is exceedingly rich in oxygen, and when it comes in contact with organic material, especially in a state of putrefaction, it becomes decomposed, and the oxygen is set free. That is, the oxygen is now in what is called its nascent state, and in that state it has a tendency to unite with whatever organic matter it may chance to come in contact.

In this way the organic matter is burned up, as it were, on the spot, and all odor and septic poison is destroyed by the action of the permanganate of potash. This solution may be used with the utmost freedom about the vessels that are to receive the dejections, and in the water-closets, in all cases where there is any offensive odor.

VENTILATION.

This is another point which should always engage your attention, for the same person, when sick, demands a much larger supply of fresh air than when well. For instance, if a healthy person requires two thousand cubic feet of breathing space, the sick person under the same circumstances should have at least three or four thousand cubic feet. Then, again, the sick man should have the air changed twice as frequently as the man in health.

Ventilation requires the introduction and diffusion of an abundance of pure air at short intervals, and a corresponding removal of the air vitiated by respiration. The movement of air in the sick-room should be imperceptible. At a temperature of 55° to 60°, air moving at the rate of three feet per second, is perceptible. Any more rapid movement than this, gives rise to a draught of air, and will endanger the patient.

It is essential that the air should be thoroughly diffused, and then be removed after being breathed once.

It is claimed by some that the "law of the diffusion of gases" will insure perfect ventilation. But this law acts slowly; whereas the vitiation of the air by respiration goes on rapidly.

Others think that the wind can be made to ventilate thoroughly. The objection to this is that the wind is not constant and incessantly varies in velocity and force.

The most reliable method is that which depends on the variation in the weight of the air by heat.

In every attempt at ventilation we are to first settle the question whether the impure air is to be removed from the apartment at the base or at the ceiling. The latter method is far inferior to the former.

If there is a hot-air register in the floor on one side of the room, and a ceiling ventilator on the opposite side, the hot air will rise immediately to the ceiling, along which it will glide, and escape through the ventilator. Meanwhile, the bulk of the air in the room will hardly have been disturbed at all, and in sleeping rooms, especially, there will be very little diffusion. We are not to lose sight of the fact that carbonic acid gas is much heavier than atmospheric air, and that the bad air will naturally gravitate to the lower part of the room. A heated flue, with an opening at the base, will remove the bad air rapidly and insure the best diffusion. The old-fashioned fireplace answered the same purpose, and is by far the simplest and best method of ventilating any sick-room.

If the chimney has a throat one and one-half feet square, with a good fire, the air will move through the chimney at the rate of four feet per second, and air will be discharged at the rate of six cubic feet per second, which would be at the rate of twenty-one thousand six hundred cubic feet per hour.

Supposing a room of the capacity of two thousand cubic feet, with a fireplace as above, and with three persons in the apartment. The doors and windows all being shut, the air would still become bad through lack of proper diffusion. The whistling of the air about the windows of such a room—fairly shrieking to get in—can always be heard.

If we now open a window farthest away from the fireplace *at the top*, diffusion and ventilation will be good enough.

If the sick-room is ventilated by a fireplace, we should always open a window at the top. If the room, on the contrary, is heated by a register, a window should always be raised at the bottom, since the hot air rises to the top of the room, creates a plenum, and so forces the air out at the bottom. There are three points to be observed in regard to the sick-room. Note, first, whether there is any perceptible odor, on entering the apartment from the open air; if so, ventilation is imperfect.

Make sure, in the second place, that there is a free inlet and outlet for the air.

And, thirdly, place an open-mouthed bottle by the side of the bed at night. In the morning, before there is any opening of doors or windows, or any movements about the room, pour a little clear lime-water into the bottle and shake it. If the air in the bottle is pure, the lime-water will remain clear; but if otherwise, it will become milky in appearance, showing carbonic acid in the air, which has united with the lime, forming a white precipitate of the carbonate of lime.

DIETETICS.

The few remaining minutes of the hour may be devoted, perhaps with profit, to a few important items with reference to the dietetics of the sick-room.

It was a doctrine taught by our grandfathers and fathers, that when a man was sick, he should first be starved, second bled, and next receive ten and ten, which meant ten grains of calomel and ten grains of jalap combined. If these measures did not cure the patient the first day, they were repeated on the second, and so on.

But I do not believe that, simply because a man is sick, or because he has some fever, he should be knocked down with the lancet or some powerful sedative agent. All these agents may be used with discretion in accordance with the principles of the old New England doctor, who achieved a remarkable degree of success in the treatment of typhoid fever. When asked what he attributed his success to, he replied, "When I enter the sick-room, I look my patient over carefully, and if he is cold I warm him; if he is hot, I cool him; and if he is about right, I let him alone; that is, I study to equalize matters as much as possible, and use drugs only when necessary."

A man, simply because he is sick, is not to be starved, nor, on the other hand, can a man who is sick, as a rule, take such articles of food as a well man would be likely to take.

It may be doubtful whether a man, when first taken sick, should take a large quantity of food, but one of the articles which he may have is *Indian gruel*, if not made too strong. If, however, you give permission that the patient may have gruel to take, unless you give special directions as to how it shall be made, you will very commonly find that the nurse has prepared a fair specimen of Indian pudding, and has been administering that for gruel.

In making Indian gruel there should be no more than a dessert or table-spoonful of the meal to a quart of water, and this should be boiled for a long time,

keeping the quantity of water good throughout the entire boiling process.

Prepared in this manner, it may be made decidedly salt, and then administered to the patient during the first few days of his sickness. There is one article of diet which all persons may take under all conditions, and that is *milk*.

There are those who say they cannot take milk, that it makes them bilious, etc.; but that is not true. A person who is sick may take milk with the greatest possible advantage, because it contains, in a form easy of assimilation, all the elements essential for maintaining nutrition. It is the natural aliment of the young animal, and certainly answers a good purpose for the old animal, provided it is used properly. New milk, I do not hesitate to say, may be taken, as far as disease is concerned, in any and every condition. Perhaps it will require the addition of lime-water, if marked acidity of the stomach is present; and perhaps a little gentian may be requisite to stimulate the stomach somewhat; and it may be necessary to give it in small quantities and repeat it often; but ice-cold milk can be put into a very irritable stomach, if given in small quantities and at short intervals, with the happiest effects. We have now come to believe, contrary to the teaching of our fathers, that *cold water*, even ice-cold water, is a most beneficial drink, and therefore permit our patients to have it as often as they may wish, provided too much is not taken at any one time.

Now, *tea*, which is a wholesome beverage, and, withal, contributes somewhat to scandal, is very comforting, especially to a sick woman, and may be given without harm, if it is sufficiently diluted with milk. When made very weak—just strong enough to give a flavor—well supplied with milk, and, perhaps, a little sugar, it gives the patient a trifle of nourishment in a very palatable form.

There is another article which has long been known in the sick-room, and that is *beef-tea*. This is not only agreeable to the taste when properly made, but it is one of the very best methods of administering nourishment. There are many who say that there is little or no nourishment in beef-tea, but it does nourish men, otherwise they could not live as long as they do upon it. I admit that bad beef-tea is not very nutritious; and it is perhaps the exception that patients get good beef-tea. It is this fact, perhaps, which, as much as anything, has led to its disuse. If, however, you will make beef tea according to the directions I now give you, it will be found to be a most serviceable article among the dietetics of the sick-room.

Take a pound of the very best beef that can be obtained in the market—the butcher will tell you that any kind of a piece answers to make beef-tea of, but that is not true—cut it into small pieces the size of the end of the thumb, place it in a pint basin, cover *cold* water with, and then place the dish upon the back part of the range or stove, where the water will gradually get warmer and warmer, but will not reach the boiling point. Let it stand and simmer in this manner two hours. Then bring it forward, and boil over a quick fire twenty minutes, and immediately after pour the fluid from the beef, at the same time allowing the little particles which become detached to flow off with it. Now, if there is any fat in the tea, it is well that it should be removed, for the reason that the bile and pancreatic secretion may be unable to emulsify it, and it may do more harm than good. If you wish to be very precise upon this point, the tea can be set aside, and when perfectly cold all the fat can be removed from the surface in a flake; or the fat may

be taken up by dropping a piece of flannel upon it as it floats upon the surface of the warm tea.

It is not a good plan to strain the liquor, because this process will remove more or less of the little particles of beef, which are very essential to the value of the tea. It may now be salted, and given hot or cold, as the patient may wish; and it may be given as soon as the pulse indicates any diminution in the force of the heart's action. What becomes of this article of diet when taken into the stomach? The advocates of the worthlessness and non-essential in beef-tea would answer that it makes but little difference. I believe, however, that it is mostly taken up by the gastric veins, and, at all events, that it is exceedingly palatable and nutritious, and does do something more than simply warm the stomach and make the patient happy for a short time.

In case the patient's stomach is very irritable, so that large quantities of any substance cannot be borne, you may resort to *beef-extract* for nourishment.

The proper method of making this article is to take a pound of the best beef, cut it into small pieces, and place it in a good-sized open-mouthed bottle—a pickle-jar is perhaps as convenient as any. Cork the bottle loosely, and then set it into a kettle of water, which is to be kept boiling for two hours. If the bottle is now removed, it will be found that it contains a considerable quantity of fluid, which may be turned off, and the beef subjected to slight pressure to remove still more.

In this fluid we have a concentrated article of nourishment, and it may be given, after it has been seasoned, either pure or diluted, according to the condition of the stomach. Beef-extract is not nearly so palatable an article of food as rich beef-tea, made in the manner described. Ordinarily, however, the tea is badly made, and contains but little beef and considerable water.

Thus, gentlemen, I have considered in this lecture small points which I believe to be of practical importance; and, although they have been referred to in a somewhat discursive manner, I trust they will prove to be of some service to you when you come to engage in actual practice.

THE INFLUENCE OF THE USE OF WIND INSTRUMENTS ON CHEST AFFECTIONS.—Dr. Burg, a French physician, has published a little book in which he endeavors to controvert, by reference to his own observations and personal experience, the notion commonly entertained that the use of wind instruments is injurious to individuals characterized by pectoral weakness. He remarks, "many philanthropists on seeing our young military musicians wield enormous wind instruments, have sorrowed over the few years the poor fellows have to live. Well, they are mistaken. All the men whose business it is to try the wind instruments made at the various factories before sending them off for sale, are, without exception, free from pulmonary affections. I have known many who on entering on this calling were very delicate, and who, nevertheless, though their duty obliged them to blow for hours together, enjoyed perfect health after a certain time. I am myself an instance of this. My mother died of consumption, eight children of hers fell victims to the same disease, and only three of us survive—and we all three play wind instruments. The day is not far distant, perhaps, when physicians will have recourse to our dreaded art in order to conquer pulmonary diseases."

Original Communications.

A CASE OF GUNSHOT WOUND OF THE BRAIN, THE BALL REMAINING.

By NATHAN MAYER, M.D.,

HARTFORD, N. Y.

On Friday, the 23th of March, early in the afternoon, Mr. M. Ballerstein, a gentleman 54 years of age, and in ordinarily fair health, was shot by accident at his place of business. The mouth of the pistol—a Smith & Wesson revolver—could not have been at a greater distance than five or six feet from his head; the ball was $\frac{2}{10}$ of an inch in calibre. He was struck on the right side of the forehead, at a point $1\frac{1}{2}$ inches from the middle line and $\frac{1}{2}$ inch above the bony margin of the orbit. He fell, and became unconscious almost immediately. The persons causing the accident left in a fright, thus leaving him alone to recover at his leisure. When consciousness returned—after a few minutes it is supposed—he was dumbly impressed with the sense of physical injury, rose, gathered his keys, and left the office, locking the door behind him. At this time he felt something trickling down his face, and now, for the first time, had distinct recollection of the accident. He unlocked the door, went to the mirror and there discovered the wound in his forehead. Still in a confused condition of mind he washed his face and then walked out once more, again locked the door, and proceeded homeward, a distance of nearly a mile. He walked the entire distance, through a populous street, holding a handkerchief to his forehead and feeling much confused. On reaching home he sat down, and said to his daughter: "Help me take off my clothes, and send for the doctor." To his wife he stated that he had "fallen and hurt his forehead."

A half hour later I was with him. He was conscious, rational, and free from pain. There was an appearance of exhaustion on his face, but those around had just administered a tablespoonful of brandy, and very soon he recovered his usual looks. A few drops of blood oozed from the wound, which presented clean edges. With great care and delicacy of touch I introduced a silver probe through the soft parts, and then, with a slightly inward turn, passed it by the ragged edge of the perforated bone into the cavity of the skull. The direction of the probe was mainly from front to back, with a slight turn upward and inward. It was advanced to a depth of $2\frac{1}{2}$ inches, where it met the resistance of an elastic body, giving a little, then bounding back—probably a membrane. Being left thus in the wound, a slight and regular vibration was perceptible. The pulse beat seventy-two, and the only general symptom that could be referred to the injury was a perceptible effort in speaking and some thickness. Sight, hearing, taste, smell, and feeling remained perfect, and no trace of paralysis or convulsion could be noticed. Perfect quiet, occasionally a tablespoonful of milk, hot things to the feet, and a cool, wet cloth to the forehead—these were ordered, stimulants and other food being expressly forbidden.

On the following day Dr. P. W. Ellsworth, a surgeon of large experience and unsurpassed judgment, who in his practice has anticipated many of the methods and instruments which have enriched surgery in the last thirty years, saw the patient with me. He introduced the probe to the same depth, and came to similar conclusions as myself, namely, that the ball had passed into the skull and lodged at some point where it caused little pressure or inconvenience. He

advised the continuance of the treatment, and deprecated further interference by operation.

On the fourth day the celebrated Professor Frank Hamilton, of New York, whose teachings have been my surgical guide during the last years of the war, and since, saw the patient in consultation with Dr. Ellsworth and myself. His opinion fortified ours on all points. He looked upon the case as very grave, and anticipated a fatal result. The probe was again introduced, but, at the Professor's judicious request, not beyond the inner plate of the skull.

Until the sixth day there was little change. The pulse remained at seventy-two, the patient claimed to be comfortable, and except some prostration and the slight indistinctness of speech, there were no general signs of injury. The first orders had been strictly adhered to, and the wound kept open by a wax bougie, which was introduced to the depth of three-quarters of an inch several times a day.

From the sixth to the ninth day the speech grew more indistinct, and the pulse rose to eighty. On the tenth day he could hardly talk, and would not swallow unless expressly ordered. The wound had been allowed to scab over, and he complained of soreness in its vicinity. Inclined to sleep much during the day, he had a slight convulsion that night, after which the right side of the face seemed drawn up a little. In the morning two more convulsions followed. A bag of ice was put on his head, and the former treatment continued. Next day (the twelfth) he was entirely speechless, signified that he had great pain in the head, and wore an expression of collapse. The scab was taken off the wound, and a teaspoonful of creamy pus spurted forth. Later in the day a string of purulent matter was found in the neighborhood of the wound. This seemed to have the effect of relieving the pressure in the head. On the following day he spoke audibly but very indistinctly, and the pulse, which had been at eighty, came down to sixty. He was perfectly conscious and rational. The wound was kept open, but no more pus came forth; and, the morning after, six leeches were placed upon the forehead and the bites encouraged to bleed for three hours. On the fourteenth day the pulse had once more risen to seventy, and the power and distinctness of speech, as well as the general strength, began to increase. His diet was ordered on a more liberal scale. Three days after, there was a slight relapse, followed by the escape of a small jet of pus, perhaps a quarter of a teaspoonful. But after this he improved rapidly, and soon demanded more solid food, seeming fairly to get well, when suddenly a great faintness overcame him in the afternoon of the twenty-first day. A few teaspoonfuls of whiskey relieved this, and now, with a steady pulse of seventy, he made quick and reliable advances. He spoke clearly, was very cheerful, read the papers, and insisted on giving some directions about his business. The weather was charming, and soon he sat up for several hours a day, and his appetite exceeded his allowance. On the thirtieth day he walked to the door, and it became very difficult henceforth to enforce the quiet and rest which I still conceived necessary. The wound, which on the twenty-fifth day after the injury could not be probed deeper than the bone, was thereafter permitted to heal up. About the 8th or 10th of May he began to take walks of some extent, always accompanied by a friend. On the 20th he walked to his office, distant a mile. Soon after he commenced to use the cars regularly, and, in fact, attended to all his duties, both in his business and the societies of which he is a member. At present he claims to be perfectly well, with this exception: once

in a great while a moment's difficulty in recalling some fact, or getting hold of some idea or word, will occur; nor is he quite so strong as before. But a dyspepsia which annoyed him previous to the accident was totally dissipated by the regimen enjoined.

HARTFORD, June 2, 1875.

A CASE OF NON-SPECIFIC RUPIA PROMINENS.

By FREDERICK WILLIAM GODON, A.B., M.D.

DAN. GREEN, a telegraph operator, *æt.* 23, applied to me for treatment on June 7, 1875, for a growth on the penis. On examination the growth was found to be a crust or scab of conical shape situated on the left side of the external surface of the prepuce. The crust was arranged in rings of a dark blue color, shading off lighter in the interspaces, where they are thinner. A thick, hard, dark bluish cap formed an apex. The base secreted a mass of yellow pus, which was confined by a thin film which supported it. At right angles to the base ran darkish streaks on the film through which pus oozed. The base was surrounded by a pinkish and inflamed margin, about a quarter of an inch or less in width, but which did not implicate the healthy skin. Vertically the crust measured three-fifths of an inch, the circumference one inch and nine-tenths. The patient stated that he had not had any sexual intercourse for two months and a half, but confessed to having had gonorrhœa a year ago. He denied ever having had syphilis, and the penis showed no marks or cicatrices, and on a careful examination I could find no evidences of constitutional disease. He told me that six days before he came to me, he noticed a small pimple on his penis, which gradually increased, despite soap and water, and the application of sweet-oil, until it assumed the dimensions already given. The patient was very pale and fair, with a large head and prominent forehead, and evidently scrofulous. He had been a great sufferer with rheumatism from childhood, unmistakable signs of which he bore. He had only been out of the hospital one week when he presented himself, where he had been laid up for four weeks with rheumatism, and his story was verified by the resident physician, of whom I made inquiries. I removed the crust with a probe, and found that a large mass of sanious, yellowish-gray pus completely filled it. The ulcerated surface beneath was covered with a thick layer of yellow pus. I ordered the patient to wash it thoroughly with white castile soap and tepid water, and to apply a lotion of carbolic acid. On the following evening the ulcer, although cleaner, still was discharging pus. Pink granulations appeared over its surface; the edges were raised and ragged.

On the 17th of June, ten days after the removal of the crust, the ragged edges had become rounded, slightly raised, and of a healthy pink color. The enclosed space was filled with healthy granulations, the secretion being slight. The healing process followed slowly, but without difficulty, and on July 16th, there only remained a white cicatrix. The skin was entirely free from eruption, and the patient gave no symptoms of constitutional syphilis.

The case is presented not only as peculiar and unique, from the unusual dimensions of the crust, and its solitary character, but is rendered additionally interesting owing to the undecided question among dermatologists as to whether rupia can occur unconnected with syphilis. Hebra denies the existence of the non-syphilitic disease of that name. He classes

all others with ecthyma, and bases his diagnosis on a characteristic vesicular ring around the base. Fox and Wilson now hold the disease to be syphilitic, while Shedel and Hillier non-syphilitic; Hillier attributing it to a profound constitutional cachœxia, and common in the cachectic condition of the system which follows upon acute specific diseases.

Copeland, in his Medical Dictionary, after defining it, gives serofula, diet, want, etc., as causing the disease. Had the case been seen in its earliest stages, the diagnosis would have been conclusive. The patient may, it is barely possible, despite his assertions and his illness and confinement, have had connection of an impure character, and so contracted it, although his scrofulous appearance and the history of his late illness seem the most plausible way of accounting for it.

SAN FRANCISCO, 103 MONTGOMERY STREET, July 17, 1875.

A SIMPLE METHOD OF ASPIRATING THE BLADDER.

By LOUIS A. LA GARDE,

ACTING ASSISTANT SURGEON U. S. A., CANTONMENT, SWEET WATER, TEXAS.

On the 10th July, 1875, a Mexican teamster, thirty-four years of age, entered the Post Hospital, with retention of urine of thirty-six hours' standing, resulting from organic stricture of the urethra. He was put on opium, and given hip-baths frequently during the first six hours of his admission. Catheterization was attempted, but failed. He refused to submit to external perineal urethrotomy, which was urged as the only means of relief in the absence of any of the modern instruments for the relief of both the stricture and retention. Having no aspirator, and the opium and hip-bath treatment having failed, the case resolved itself into one of rectal or suprapubic puncture of the bladder. A happy idea occurred to me, which I received from my friend, Professor Griffith, of Kansas City, in conversation last winter. I contrived an aspirator by means of a vacuum created in a quart bottle, in which was poured 3 ss. of chloroform, allowed to evaporate by heat in a water-bath near the boiling point. While the last of the chloroform was evaporating, the bottle was stopped with a tight fitting-cork, through which a canula was tightly adjusted. I attached a piece of India-rubber tubing, twelve inches in length (from a Davidson syringe), to the end of the canula, and fixed a hypodermic needle in the other end of the tube. Having everything ready, I thrust the needle into the bladder, two inches above the pubes, in the linea alba. From the fact that the bottle was still warm, and the remaining chloroform, in a state of vapor, occupied the space in the vacuum, the urine did not flow for perhaps ten minutes; but as soon as the condensation of vapor commenced to take place, the urine was seen to come through the canula, at first drop by drop, and then into an uninterrupted stream. It continued to flow thus until the bottle lacked not more than two cubic inches of being full. The amount of urine removed measured two pints.

The morning following the operation the patient passed urine through the urethra, and later on in the day his condition was so much improved that he considered himself well, and insisted on leaving the Hospital.

I have never noticed an account of aspiration ever having been practised in this simple way, and I am thus prompted in reporting the case. The idea is not mine, as I have said before.

APHTHÆ OF PHTHISIS.

Aphthæ sometimes becomes an exceedingly troublesome affair, especially in the latter stages of phthisis. The following mixture was recommended, which can be applied with a brush, or the patient can rinse the mouth with it.

One grain of either quinine or morphine (sulphate) to an ounce of water, and to this add one drop of the oil of black pepper.

FOR THE RELIEF OF THE THROAT IN PHTHISIS.

It not infrequently happens that the chief thing of which the patient complains is the throat, and when it is examined evidences of pharyngitis and more or less of follicular inflammation is quite likely to be seen. For the relief of this condition, salt water and oil of black pepper, used in the form of spray, was recommended. The solution of salt should perhaps

be no stronger than that made by adding a teaspoonful of common table salt to a pint of water, and oil of pepper added in the proportion of one drop to the ounce.

VOMITING IN PHTHISIS.

The explanation given, when it occurs in the first stage of the disease, was that it is produced by pressure of the enlarged bronchial glands upon the *par vagum*. Dry cups between the scapulae, it is said, will arrest the vomiting in this stage very quickly. In the advanced stages of the disease the enlargement of the bronchial glands disappears, and the vomiting depends upon another cause. For example, the patient commences to cough in the morning to remove collections of mucus and pus which have accumulated during the night, and as the muco-purulent or purulent material comes into the mouth, its taste and offensive odor produce nausea and vomiting. Absorption of septic material also enters as a factor when cavities are present. To relieve the symptom under these circumstances carbolic acid was recommended. These theories must be taken for only what they are worth. The therapeutics have some value.

DIARRHŒA OF PHTHISIS.

An excellent article of diet when this symptom is present is milk boiled with mutton suet until it is thick as cream. The method of preparing it is to put a piece of suet into a bag and boil it in the milk until the requisite consistency is obtained. To this may be added such remedies as the physician may wish to administer, as persulphate of iron, opium, belladonna, etc. Belladonna is said to be very serviceable, for the reason that it possesses the power of producing contractions in the unstriped muscular fibre of the intestines. The following pill was also recommended:

℞ Resin of turpentine..... gr. iij.
 Nitrate of silver..... gr. ʒ.
 Opium..... gr. ʒ.
 M.

S. One p. r. n.

Any of the oleo resins, perhaps, may be used.

RHEUMATISM.

It has been said that rheumatism is quite apt to follow in the wake of some chest trouble, such as asthma, phthisis, etc., and there were several cases in the wards which seemed to illustrate this idea. They were, for the most part, cases of phthisis, and the prescription in use was denominated that for "rheumatism of phthisis." One or two or more joints became more or less swollen, stiff, and inflamed, and the patients were placed upon

℞ Potass. iodid..... ʒ i.
 Fld. ext. conium..... ʒ iij.
 Tr. opii. camph..... ʒ ii.
 Aq. aurant. flor..... ʒ iv.
 Aquæ..... ʒ iv.

ACUTE PLEURISY—ACUTE PERICARDITIS.

The pleurisy in this case was apparently idiopathic. If there was anything which predisposed the patient to the attack, it was the influence of alcohol. The pericarditis followed the pleurisy and was of moderate severity.

ACUTE PNEUMONIA.

By this term is meant the ordinary croupous pneumonia of adults. Of this we saw several cases: some were convalescent; some were in the resolving stage; and some were in the stage of complete hepatization. One man who came into the hospital with delirium

tremens was suffering from double pneumonia, which had been preceded by pleurisy upon the right side, and at this visit a marked pleuritic friction sound was heard for the first time upon the left side. There was marked bronchial breathing over the right lung posteriorly. This man had had a few leeches applied to his chest, and was being dry-cupped daily.

The saying that large doses of quinine will reduce the temperature for any considerable length of time, had not been confirmed by the experience of the hospital. There is another item with regard to the treatment of these cases of pneumonia which in these days should be noted, and that is, cold applications to the chest had *not* been used. Oil silk is usually applied. The treatment in the main has been expectant, and the rate of mortality has been very low.

ACUTE RHEUMATISM—PERICARDITIS.

The chief point of interest was the occurrence of pericardial inflammation in the course of acute inflammatory rheumatism after the urine had been made alkaline. It has been claimed that this does not occur.

HEMOPTYSIS.

This patient expectorated blood quite freely while we were standing by her bedside. One lung was in the second and the other in the third stage of phthisis. She was at once ordered to take fl. ext. ergot, gtt. xl., every four hours. She had had an attack a short time before, which was apparently arrested by this remedy. At least the hemorrhage ceased while she was taking the medicine.

EMBOLISM OF THE MIDDLE CEREBRAL.

There were some interesting points in the history of this case. There were present a mitral systolic murmur and a moderate amount of hypertrophy of the left ventricle. He was suddenly attacked with right hemiplegia *without* loss of consciousness. Diagnosis of embolism of the middle cerebral artery was based upon the above data. It has been said that these cases always prove fatal, and prognosis was made in this case accordingly.

Power returned in the arm first and in leg afterward, and the patient was nearly well.

SURGICAL DIVISION.

DR. WENDOVER, HOUSE-SURGEON.

EMPHYEMA.

The special interest in this case consisted in the method of treatment, which was free incision through the chest wall, and washing out the pleural cavity with a solution of salicylic acid of the strength of one part to five hundred of water. The man was doing very well indeed, and the cavity had diminished in size to such an extent that it now held only four or five ounces. The opening showed considerable tendency to close, and for a time it was dilated with sponge-tents, but these gave the patient so much pain that he preferred to have it forcibly dilated with the finger when the cavity was emptied and washed out. His general appearance was good.

SYNOVITIS OF KNEE-JOINT.

The feature of special interest in this case was the appearance of a swelling on the second day of the effusion, about four inches above the joint on the inner and under surface of the thigh, which went on to suppuration.

How could this abscess be accounted for? Was there any relation between it and the synovitis? There was no history of injury of any kind.

ELASTIC LIGATURE.

Several cases of fistula in ano have been treated here of late, by means of the elastic ligature, and the patients have suffered but little inconvenience while the ligature was cutting through. They were up and about most of the time, and suffered but little pain. In one case the ligature cut its way through in five days; in two other cases in seven days, and in every case a fine granulating surface was left behind, which healed much more readily and satisfactorily than the wound made by the knife.

RIGHT HEMIPLEGIA—APHASIA.

The following case illustrates the difficulty at times in making a diagnosis: A female patient, *et.* 34, was admitted to the hospital on the 28th inst., with complete hemiplegia upon the right side, attended with aphasia. The pupil upon the affected side was slightly dilated, and did not respond to light. For more than a year she had complained of attacks of numbness of the right arm, lasting for a day or so, and then passing away. On the evening of the 27th she went to bed, feeling usually well, except slight numbness of the right arm. The following morning, while rising, she fell upon the floor, and was found paralyzed upon the right side. There was no loss of consciousness. There was no cardiac disease; no history of rheumatism. There was no evidence of febrile movement, as might be expected where a clot has been formed. Cerebral hemorrhage does not commonly occur until after forty years of age. Embolism is more likely to occur in younger subjects. What was the lesion in this case? Four days after admission changes in temperature were noted as follows:

Paralyzed side.	M. 100 $\frac{1}{2}$ ° F.	Sound side.	M. 99 $\frac{1}{4}$ ° F.
	E. 100 $\frac{3}{8}$ °		E. 99 $\frac{1}{8}$ °
Fifth day,	M. 100 $\frac{1}{8}$ °		M. 98 $\frac{1}{2}$ °
	E. 100 $\frac{1}{2}$ °		E. 98 $\frac{3}{8}$ °

Later, the temperature was higher upon the unaffected side, but this was accounted for by the bed-sore which the patient had upon that side. The temperature, as a whole, was regarded as favoring the supposition that the paralysis was due to cerebral hemorrhage.

CHRONIC SYNOVITIS.

The point of special interest in this case relates to the treatment. The woman was admitted to the hospital with acute articular rheumatism, which finally resolved itself into a synovitis affecting the right knee-joint. The joint became enormously swollen and tender, and the general condition of the patient bad. General remedies and local remedies had been employed without avail, and it was suggested that leeches should be applied. The patient was anemic, debilitated, and certainly this treatment did not have the appearance of being very judicious. A few leeches, however, were applied, and they apparently rendered very great service. The patient expressed herself as feeling relieved at once, and the appearance of the joint denoted improvement. The swelling diminished perceptibly immediately after their application. Confining our attention to this case, the conclusion was unavoidable that there was distinct improvement after leeching the joint. After an interval of ten days a second application was made. This was followed with treatment by means of compressed sponges, and the patient can now, at the expiration of four months, walk with only a slight limp.

THE CONGRESS OF GERMAN NATURALISTS AND PHYSICIANS is to be held in Gratz, from the 18th to the 24th of September.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, September 4, 1875.

THE INTERNATIONAL MEDICAL CONGRESS OF 1876.

EVERYTHING in Philadelphia at the present time bears the impress of the coming Centennial. Articles of manufacture, of utility, and of luxury seem to have been rebaptized with the one magic word, which, in these times of feeble reaction, gives them vitality, and it is presumable renders them more infallibly saleable. The medical profession has not escaped the epidemic, and is even now preparing the intellectual feast to which all the world "and the rest of mankind" are to be invited during a portion of an autumnal month of 1876. We hope the dishes to be spread before the guests—especially those from abroad—will be such only as are likely to be palatable, and that the caterers will not err in providing embarrassing quantity in lieu of more digestible quality. There is frequently at public banquets—and those of a purely intellectual character are also amenable to the criticism—a failure in kind rather than in degree; a tendency, in other words, to overtax the organs of assimilation with a chaotic variety of dishes, some of which are pretty and attractive to the eye, but essentially frothy and indigestible. Unless the hosts produce a *carte* of wholly nutritious viands, we fear the guests may carry away with them only the recollection of the thin and insipid rather than that of the solid and substantial. We learn that the arrangement of the preliminaries for the meeting of the Congress has now passed from the single hands of the Philadelphia County Medical Society—which, however, deserves the credit of inaugurating the movement—and that all the medical societies of that city are harmoniously co-operating to accomplish a result as grand in its perfection as in its design. The whole profession is therefore astir, without the probability of cliquism or feud, and much greater success is possible than if a mere fragment had overtaxed its energies and perhaps only feebly developed a gigantic enterprise. Time

alone will determine whether even the whole local profession, as represented in committees organized for that purpose, will be able to give to the Congress so ennobled a position among the International Congresses of the world, that it may be ever memorable for the amount of zealous, earnest work accomplished, and for the immediate and remote effects for good that may follow in its train. We urge upon all those interested in its success, that it shall not, in a single particular, pale its uneffectual fires before the radiance of any of its elder Congressional sisters. We noticed recently in our columns the fact that a portion of the programme included the delivery of addresses by distinguished authorities on a number of general branches, the speakers to be Americans only. We understand that a slight change in this plan of the entertainment will probably be effected to render it less exclusive in its nature. We trust that our Philadelphia friends will bear steadily in mind the international feature of this literary festival, and that prudence and foresight will be exercised to prevent it from degenerating into one of a purely national character. We suppose the Sections—if such there be—will afford a field for discussion on matters of vital moment that are intertwined with the health and happiness of every nation that may be represented in this Congress; but the general body of the Convention, before it is cut up into sectional partitions, will doubtless solicit opportunities of listening to those who come from over the seas not as auditors merely, but to lend the voice of their experience to the deliberations. A Centennial is seldom vouchsafed to us, and it is therefore natural that we should seize the opportunity to tell the world of our wonderful progress since the days of 1776, but this must not be done offensively or boastfully. We must not flaunt in the faces of our foreign guests the vanity, real or reputed, with which we are already accredited by the world at large. We must not claim for ourselves originality for operative procedures, therapeutic ministrations or histological researches, which may have been imported from abroad, and so familiarized among us that we may have forgotten their foreign authorship. We must not invite our professional friends to stand amazed at the greatness of the American eagle, and to wonder at the loudness of his screech; we must rather give them a few of his choicest feathers, to preserve as mementos of their visit. And while we naturally imbue the Congress to a limited degree with the spirit of self-glorification, which seems absolutely inseparable from it, let us hope also that we may become more earnest and profound thinkers and wiser practitioners, from the infusion into the mass of the leaven which will enter it from agreeable professional and social partnership with the representatives of culture and science from abroad. As the plans of the Congress become more fully developed, we may possibly again offer such unsolicited advice as we think may tend to increase the

efficiency and completeness of the undertaking, for the time will soon come when it must of necessity assume vast proportions and cease to be an enterprise in private hands, as we might style those of the profession of any one city.

THE SURGERY OF THE SIAMESE TWINS.

A very recent addition to Chang and Eng medical literature is a paper read May 5, 1875, before the College of Physicians of Philadelphia, by Prof. William H. Pancoast, and published within a few days in its volume of Transactions. The surgical considerations in regard to the propriety of an operation for the separation of the twins, deduced from the autopsy made last year, form the subject-matter of the paper. The conclusions arrived at are, I. That as a necessary deduction from the anatomical demonstration of its constituent parts, no operation of section of the band, for the purpose of separating the twins in adult life, could have been performed and their lives preserved. II. That it would have been judicious surgery, upon the death of Chang, to have at once applied a strong ligature around the band, as far as possible from the body of Eng, and then to have cut through the band, between the ligature and the body of Chang. III. That whether or not the operation would have been successful in the childhood of the twins is problematical, but that it would have been the part of wisdom and humanity to have made the effort.

The volume contains also Dr. Harrison Allen's very interesting report, in full, of the autopsy of the same teratological curiosities, technically classed under the variety of abnormal conformation known as the omphalopagus xiphodidymus. From the fact of a certain amount of continuity existing between the portal systems and that in the foetal and early period of extra-uterine life, the vessels must have been more capacious, and associated with a large tract of liver tissue, he concludes that, all things being equal, an attempt at division of the band in early life would have been accompanied with more serious hemorrhage than at any subsequent period.

UNSUCCESSFUL PRACTITIONERS.

OUR correspondent DIPLOMA writes a very interesting, instructive, and suggestive letter, detailing the experiences of an unsuccessful practitioner. Although we are not prepared to endorse everything he says, we believe, from what we know of the writer, that the facts which he presents are not to be questioned. A great many of our readers will think with us that the time has come for looking the matter of overcrowding of the profession fairly in the face, and hold the medical colleges of the country to an accountability. It may be conceded that there is always room in the front ranks of our calling, but in the confusion of struggling multitudes is there an even chance that the truly meritorious one will always succeed?

Progress of Medical Science.

STATISTICAL REVIEW OF OPERATIONS FOR TUMORS OF THE SUPERIOR MAXILLA.—Dr. Ohlemann, of Bremen, has furnished in tabular form the statistics of thirty-two cases of tumors of the upper jaw, where complete or partial resection was done. It appears that the entire jaw was removed fifteen times, and part of it twice, for carcinoma. Five sarcomatous tumors classed as giant-celled, three as spindle-celled, one as round-celled, and one as medullary, were operated on. Cylindromata twice required partial resection; epitheliomata twice an almost complete resection; an enchondroma once a total resection. Out of twenty total resections there were three deaths and seventeen recoveries, while of twelve partial resections there was no death. Fifteen per cent. therefore represents the total mortality. Dr. O. calls attention to the much larger proportion of carcinoma than of medullary sarcoma among these cases than in those of O. Weber. He finds that carcinoma is much more frequent in middle and advanced life, and is twice as frequent among men as women. He thinks that in some cases the tendency to the disease is undoubtedly hereditary. After the sixth month, the pain, inconvenience, and disfigurement make the patient generally quite ready to submit to an operation.

The ultimate result of the cases of carcinoma was fatal after an interval of from one to three years, the disease recurring in the cicatrix. Still he considers that the operation should be undertaken in these cases, provided the disease be not so far advanced as to make it impossible to separate the diseased from healthy tissues, because it prolongs life and alleviates suffering. In cases of epulis, the operation, with the aid of Liston's forceps, has in all cases resulted in cure. The operation itself was generally performed with the patient sitting up, the head supported on the breast of an assistant, and it was the subject of remark how well so severe an operation was borne. The incisions in the skin had to be variously modified in view of the size and situation of the tumor; but it was found that some disfigurement from sinking in of the cheek, and distortion of the mouth by contraction of the cicatrix, were unavoidable. The only exceptions to this were in two cases where the tumor grew in the direction of the nasal cavity, when Dieffenbach's incision was made use of with the best results, and in some cases where the growth sprang from the alveolar process, and no wound of the skin was required in its removal. Liston's bone forceps were used for detaching the upper jaw from its bony connections, and Langenbeck's forceps for removing the loosened portions. After thorough removal of all diseased tissue, the wound was filled with carbolized lint, and the edges united with sutures. In the after-treatment it was thought very important to prevent the flow of secretions from the wound into the mouth, through the opening left in the palate. Antiseptic solutions were therefore assiduously used so that pulmonary complications should not be set up. Secondary hemorrhage led to a fatal result in two cases, and erysipelas also occurred, mainly owing probably to the bad sanitary surroundings in the hospital. Patients usually were able to leave the hospital, cured, after from two to four weeks. Dr. Ohlemann furnishes the details of seven cases, to illustrate various points on the subject.—*Archiv für Klin. Chirurg.*, xviii., 2, 1875.

AN ANTIPHLOGISTIC METHOD OF DRESSING OPERATION WOUNDS.—Mr. Jonathan Hutchinson says that for some time past he has been employing a plan of dressing operation wounds which has afforded excellent results in the way of primary union, though he does not claim anything new for it. The essential feature of the plan is to keep the parts cool, by the systematic application of a lead-and-spirit lotion. The lotion consists of half an ounce of liquor plumbi, and an ounce and a half of spirit to the pint. An ample fold of lint, wet in this, is applied to the skin over and around the wound, and emphatic directions are given to the nurse to moisten it every quarter of an hour or every half hour, according to the rate at which it dries. The skin ought to become whitened by deposit of lead. The application is to be commenced from six to twelve hours after the operation, and from that date all bandages are to be set aside, and the lint kept simply laid on the part. It is to be continued without intermission until the wound is perfectly sound, a week or two weeks, as the case may be. During the night every suitable opportunity should be used for rewetting the lint. If the plan fail, it will in all probability be, he says, from negligence in this matter. The theory of the plan is, that by keeping the parts quite cool, and saturating the tissues with lead, inflammation is prevented. It appears to have no risks, except that if very thin skin flaps have been left, it may be possible to over-cool them and cause gangrene. Mr. Hutchinson says that he has been in the habit of speaking of this plan of treatment as antiphlogistic, but it may be antiseptic as well.—*The Lancet*, June 26, 1875.

A FOURTH SERIES OF FIFTY CASES OF OVARIO-TOMY.—Mr. T. Keith, Surgeon for Ovarian Disease to the Royal Infirmary, Edinburgh, has just published his fourth series of fifty cases of ovariectomy. The previous ones were reported in *The Lancet*, September 7, 1867, August 29, 1870, and November 16, 1872. Since the last date he has been able to diagnose and cure by a single tapping four cases of serous cyst of the broad ligament, which tumors some time ago would probably have been removed by operation. In the first series of fifty cases there were eleven deaths; in the second series, eight deaths; in the third, eight deaths; and in this last, six deaths.

In these last six fatal cases the cause was septicaemia. He says that the first was a case of acute suppurating cyst with pyaemic fever. It seemed a hopeless undertaking, but equally hopeless-like cases of suppurating cysts had recovered. In two the tumors were malignant, and in both there was red serum in the abdomen, and pleuritic effusion at the time of operation. In two the operation was very prolonged—three hours in one, nearly two in the other. The latter was a badly constituted woman, and had suffered from acute kidney affection, with convulsions. In one case drainage was used. Earlier operation, he thinks, might have saved both. In the last fatal case the patient was perfectly well until the sixth day, and recovery seemed sure. In a few hours the temperature rose to 106°, the pulse to 170°, and she died four days after. He concludes as follows: "Further experience has satisfied me of the value of the actual cautery in the treatment of the pedicle, and I am coming to the conclusion that it is the best of all the intraperitoneal methods for securing the pedicle. At first I was prejudiced against this method, and only used it in the worst cases, where the clamp could not be employed. It has had from me a very severe trial, and when the numbers are larger, I shall publish the whole of the

cases in detail. This method, as is well known, was introduced by the late Mr. Baker Brown, and after having all sorts of improved clamps, I have gone back to the simple rough method so successfully used by him."

Sulphuric ether was used in all the cases.—*The British Medical Journal*, June 26, 1875.

RESECTION OF THE UPPER JAW PERFORMED WITH THE HEAD HANGING BACK (ROSE'S METHOD); ACUTE ANEMIA; RELIEF BY ARTERIAL TRANSFUSION.—Dr. Max Müller, of Cologne, furnishes a history of a case where he practised resection of the upper jaw for an epithelial canceroid, and adopted the hanging position of the head recommended by E. Rose. It was followed by a most alarming hemorrhage, which nothing in the circumstances of the case had led him to anticipate, and which far exceeded the loss of blood in any other one of the twelve cases in which he has performed this operation. The patient, an officer in the army, thirty-eight years of age, began to suffer from the growth, in the spring of 1874, and by November of that year it had increased so as to involve the whole of the hard palate on the right side, and the alveolar process of that side in a cauliflower growth, into which a needle would easily penetrate for an inch without encountering bone. The operation was done on November 14th, the position being that referred to, and the patient being thoroughly anesthetized with chloroform, which was well borne. The object aimed at, of preventing the entrance of blood into the trachea, was completely attained. The operation was the ordinary one. The hemorrhage, however, was unusually abundant, although all bleeding vessels were promptly secured. The anesthesia passing off, the patient fainted the moment he was placed in the sitting posture on the table for the adjustment of the sutures. The head was replaced in the low position, and various measures resorted to, but no pulse could be felt at the wrist until the legs were enveloped from below up with elastic bandages. Nor was it possible to remove these, in spite of the pain they caused, after his return to consciousness, without the immediate failure of the pulse. Accordingly, after some hours' trial of other measures, the left radial artery was exposed, and nearly eight ounces of defibrinated human blood injected. The transfusion was well borne, though followed by a chill and sweat, and the next morning the patient was out of danger. He made a good recovery.—*Archiv für Klin. Chirurg.*, xviii. 2, 1875.

A PECULIAR FORM OF SKIN DISEASE.—Dr. H. S. Purdon, of Belfast, furnishes a description of an affection of the skin which he has often observed during the last nine years among the "doffers," so called, in the "spinning-rooms" of the flax-spinning mills. The "doffers" are mostly young girls, whose duty it is to take the bobbins from the machines and clean and oil them. The temperature of these rooms is always high, so that the girls are constantly in a profuse perspiration. The orifices of the sebaceous and sudoriferous glands being thus constantly dilated, become clogged, as Dr. P. thinks, with the train-oil used upon the machinery. The secretion thus retained acts as an irritant, causing an inflammation, accompanied at first by a papule, which soon becomes a pustule with a black spot in the centre. They rarely, however, burst or form a scab. He describes it as a combination of acne and lichen. It occurs chiefly on the forearms and arms, or those parts most exposed to the action of the oil, and when seen upon the face is probably due to wiping it with the oily hands. The skins of these girls soon acquire a dry yellowish quality, and the

papules, from their "shotty" hardness, and the pustulation which follows, have, when accompanied with febrile movement, given rise to the suspicion of small-pox. Dr. P. does not give the results of treatment, but none seems likely to be very effectual so long as the patients continue their occupation.—*Lancet*, Nov. 21, 1874.

A NEW KIND OF POISONOUS DRESS GOODS.—According to a report by Prof. Gintl, in the *Lotos*, it appears that the public is exposed to a new source of poisoning from the use of arsenical glycerine and the arseniate of alumina as mordants. He states that these substances are now coming largely into use, especially among the English and Alsatian manufacturers of cotton printed goods, as substitutes for albumen which is much more expensive, some substance being required to fix especially the aniline colors, which are now so much in demand. Such goods have recently been sold in Austria and especially in Prague, containing, according to Prof. G., as much as 15 to 25 grains of arsenious acid, in the form of arseniate of alumina, to the yard; and this is by no means an insoluble salt, but one more poisonous than the much abused green arsenic colors. The more suspicious fabrics are stated to be those of a violet ground with white figures, and those printed in brownish yellow or reddish brown designs, and which are sold at low prices.—*Rundschau*, Feb. 28, 1875.

ON THE PASSAGE OF WHITE BLOOD-CORPUSCLES THROUGH THE WALLS OF THE BLOOD-VESSELS.—In noticing a recent article by Prof. A. Arnold, on the migration of the "Colorless Blood-Corpuseles," Dr. Dollinger refers to A.'s former article in *Virchow's Archiv* on the "Diapedesis," or passage through the walls of the blood-vessels of the red globules. With regard to the latter, the statement is that the red corpuscles make their way into the surrounding parenchyma through stigmata which are enlarged into stomata, and that these are found not merely at the points of contact of the angles of the endothelial cells, but also in the other markings of their surfaces, and that an outflow of serum takes place through these stomata until they are plugged by the corpuseles in their passage. The process is said to be perfectly analogous in the case of the colorless corpuseles, nor can they be seen to make their way through any other openings. It is found, however, that in case of stasis the stigmata are much more enlarged than in inflammatory hyperæmia, and at the same time the accompanying outflow of serum is much greater in the former than the latter. Thus in the former case the current of serum is strong enough to divert from their course and draw towards and into the openings those red corpuseles which are passing along in the middle of the vessel, while the weaker current of serum in inflammatory hyperæmia is only sufficient to draw into the orifices the white corpuseles which move along near the walls of the vessel, leaving the red ones in mid-stream unaffected. The actual passage of the white corpuseles through the walls of the vessel is effected by their own amoeboid motion.—*Rundschau*, May 25, 1875.

EMBOLIC ANEURISMS AND THEIR ANALOGY TO ACUTE CARDIAC ANEURISM.—In several cases of endocarditis affecting especially the aortic valves, Ponfick has found multiple aneurismal enlargements of the vessels, notably those of soft tissues, such as the brain and mesentery. In their interior was found an embolus consisting of a rough calcareous mass, resembling the excrecences on the valves of the heart, and the plugs which occur without aneurism in other arteries. He

attributes the formation of the aneurisms to these emboli becoming more and more firmly wedged into the vessel, and penetrating its walls either by necrosis from pressure, or by their pointed extremities, whence follow hemorrhage, and the formation of a sac. He states that they are most commonly found just behind the point where a vessel subdivides, the action of the stream of blood in this situation having a tendency to force them against the wall of the vessel, and so favor the formation of the aneurism. In calling attention to this matter, Bettelheim cites Rokitsansky's analogous explanation of the formation of acute cardiac aneurism, viz., by necrosis of the heart wall, caused by the constant pressure of vegetations springing from the aortic valves. Ponfick believes that a large proportion of the blood-sacs occurring on small arteries can be traced to such an origin.—*Virchow's Archiv*, 58, 1875.

Correspondence.

THE EXPERIENCES OF AN UNSUCCESSFUL PRACTITIONER.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Davids are always singing the attractions of the medical profession, and never lack an audience; Jeremiahs utter their lamentations in vain, and are of no account.

Nevertheless, I have reason to think that Jeremiahs are by far the more numerous, and have a good deal on their side. As one of the Jeremiahs, therefore, I trust I may be allowed my growl, if only for fair play. If what I write savors of egotism, I here once for all make a humble apology; but egotistical or not, my only wish is to set down the facts of my case, now that I take my leave of medicine, for others' benefit.

About eleven years ago I commenced the study of medicine, immediately on graduating from one of the best literary colleges in the country.

After three years spent in hard study and faithful attendance on lectures, I took my degree at Bellevue Hospital Medical College; then I passed the examination, and commenced my term of service in the Hospital (Bellevue). On the expiration of my eighteen months I went abroad, and spent a year of hard work in Germany.

On my return I received the appointment to the surgical class of a large dispensary, and also opened an office in a thickly settled district near Washington Parade Ground.

I wrote several articles for the medical journals—indeed you published some of them—on which I was complimented by many of the older members of the profession. Then I joined different societies, and employed my ample leisure in working at chemistry, and with the microscope, and in reading the journals. So you see, my education was much more extensive than that usually enjoyed by students.

I trust these details will be pardoned. I wish to show that the oft-repeated story of non-success from coquetting with your business, and allowing other concerns to take your time was not the case in this instance.

This was all very well, and gave me great pleasure in the doing, for I was an enthusiast about medicine, and would have liked nothing better than to have

pursued it for its own sake; but, unfortunately, the profession had been adopted by me as an ultimate dependence for necessary bread and butter. Now, my neat and elegant account-books showed, at the end of the second year in city practice, just two entries, relating to two patients, from neither of whom had anything been collected.

I saw my capital dwindling, and resolved to make a move at once, as I could not afford to remain longer where I was.

My location was changed to a town beyond the immediate influences of the metropolis, nearly one hundred miles away from the city. It was a place of some four thousand inhabitants, many of whom were very well off, and as there were but three physicians there, I thought a fourth might find something to do.

Well, the first year I made \$500, barely enough to cover expenses for living, a horse and wagon being indispensable in a place where often I had to ride many miles. The work was hard; that I had bargained for, but the bane of the place was its "beat" element. Had half of those who consulted me paid, and most of them were fully able to do so, I would have done a stunning business; as it was, my \$400 just represented the payments of one-fifth of my patients, the remaining four-fifths being still my debtors.

The second year saw the \$400 of the first sink to \$100. The cause of this phenomenon is easily explained. One of the original, old-established doctors died, and as soon as the fact became known, a certain shrewd individual from New York made up his mind that he could not do a better thing than to come here and give himself out as the successor to the deceased doctor. Unfortunately for his calculations the same intention animated the minds of no less a number than five equally shrewd individuals, and Beeler's Quarters was plethoric with doctors. These new comers at first set about to vindicate, each for himself, the title of being the only original Jacobs. But competition did not enliven trade, and at last things got so bad that each man of the six set up a private dispensary of his own, and quarrelled with his neighbor over the few charity patients who ventured on availing themselves of the abundant provisions for medical relief. Finally, poor people were induced to submit their ailments to one of the dispensary practitioners, who had the reputation of always prescribing tinctures, and as the opposition made use of fluid extracts, the practice of the alcohol man grew apace. But the six soon tired of this business of competition and free dispensaries, medicine included, and then they banded themselves together into a mutual benefit and admiration society against an innocent though unappreciative community.

Since the spring floods from the medical colleges, four newly made graduates have added themselves to our number, they likewise having heard that there was a dead man's place to be filled, and supposing, in their ignorance, that they had found "an opening." I need not dilate on the effects of all this on my business. When I tell you that since the first of February, 1874, up to the present time, I have pocketed the magnificent sum of \$50 from my practice, I have reason to believe that I am ahead of some of my fellow unfortunates. This is not all. There have lately come here a rubbing doctor and his wife, who at once set every sick and imaginary sick person mad on the subject of their peculiar practice. Not only we, late comers, but the old and well-established physicians of the place have been made to suffer by the seductive pamphlet's influence. It is not only the ignorant that patronize these people, who are a pair of as pestilent,

vulgar, and ill-educated quacks as it has ever been my ill-fortune to meet, but the most prominent and intelligent minister of the place has sent his wife to be rubbed, and the valetudinarians of all the churches followed the lead.

When the man of greatest importance in the town is gained over by a discourse on the certain efficacy of expelling disease—as an entity—by rubbing and stimulating "the pores," what chance can a modest professional sign have as attraction, when placed in competition with a lively colored representation of a joyful ex-cripple throwing away his crutches at the touch of a long-haired individual near by.

To-day I say good-by to the profession. It is greatly to my regret to be obliged to do it. Willingly would I wait the ten years which the gentlemen under whom I served at the hospital tell me will bring success, for my desire is, above all things, to remain in the ranks. But stern necessity knows no law of choice.

Nearly eleven years ago I commenced with a capital of eight thousand dollars, which I expected would pay for education and give me something to live on till my practice should be sufficient to bring me a living. The facts show that I have nearly consumed my capital, and am farther than ever from the chance of making a living by medicine. I shall take the thousand or so I have left and try to get in some mercantile business, which, no matter what it may be, can hardly promise worse than the certain starvation if Medicine be longer relied on. Fortunately I have only myself to consider; if I fail in a new undertaking no one will be dragged down with me. What is the secret of my non-success? It is not repulsiveness of person; it is not lack of decent manners; it is not extreme youth; it is not excessive age; it is not inattention or want of earnestness in such business as I have had; it is not the commission of some unfortunate mistake which has shaken people's confidence; it is not lack of proper technical education, yet even the hod-carrier makes more money than I, and I pay the girl in my kitchen a stipend far beyond the amount of my own receipts.

I recollect hearing a genial and popular professor once, giving his closing lecture to his class, say: "Gentlemen, a great many of you, over a hundred and a score, will be sent out from this school this year—many more from all the schools over the land—and besides, there is an absolute increase in the number of physicians here; but we want all of you; this great and growing country cannot have too many."

Then came something about "our glorious, our noble profession," which was applauded to the echo.

Now, I respectfully submit this is all wrong. Platitudes are very well, but when young men—farmers' sons and mechanics—stimulated by such misplaced eloquence, hold their familiar tools in contempt and make up their mind to become doctors, I emphatically declare that the man who urged them on has done a great wrong to the young men mentioned, to the community, and to the profession. If there is one thing more certain than another it is that this "great and growing country" does *not* want more doctors. I am no hand at statistics, but in Great Britain and Ireland I believe there is a population about as large as ours. There there are some twenty thousand doctors, yet from nowhere else is more complaint made of the overerowded state of the profession. In our country, the last census, if I recollect rightly, made the number of medical men, of all schools, seventy-four thousand—one to every five hundred and forty persons. Considering the gigantic abuses to which medical charities in large cities are subject, and the

many paying patients who select long-established physicians, of great reputation as their advisers, how miserably minute a fraction of that five hundred and forty comes to each of the juniors.

It cannot be otherwise.

Now I should be the last man in the world to prevent any one, who really has a decided inclination and aptitude for medicine, from qualifying himself to practise it; but that inclination ought to be founded on a better basis than the fancy pictures drawn by our professors. They are gentlemen usually—in the cities—in large and remunerative practice, and they must remember that everybody cannot be as they by any amount of work. When every place is full, how are new-comers be accommodated?

But even if a man know without doubt that medicine is his proper vocation, I warn him, by my example, not to try it if he looks to get his support therefrom. It is true that many a young man has the way made plain for his feet by doting relations and friends, who nurse the second Mott through adversities which would have swamped him unaided. Again, there are instances of blind luck, in which certain favored individuals stumble right into a certain success; but who be to him who promises himself a certain leap at success on no other ground than that others have accomplished it before him. He will find the way blocked by scores of eager contestants, each bent on the one object, and which necessarily but one can obtain.

Another strange feature about the profession—a feature which distinguishes it from other learned callings and from trade—is, that money and brains, and time spent in perfecting one's self in medicine, give the man who has thus qualified himself no advantage in competition when seeking the patronage of a community. I was told by physicians of great reputation and first-class metropolitan practice, that by going through Bellevue, and studying awhile abroad, I would put, in a few years, thirty thousand dollars in my pocket. Perhaps that "few years" is not up yet; but certainly in five years the first thousand has not yet come to me. I wish to be distinctly understood as putting the incalculable and no-where-else-to-be-found advantages of hospital interne service on a higher level than that of a mere monetary investment, nor did I ever suppose that study at home or abroad would ever enable me to secure anything like the returns which flow into the coffers of a certain carpenter, turned quack, of whom I have knowledge. Nevertheless, there is certainly some excuse for the dissatisfaction of a man who, on the earnest recommendation of several eminent veteran Æsculapians, reduced still farther his slender remaining means, that he might secure a thorough training for his work, and in five years after finds that the army of medical college graduates, whose whole education comprises the two courses of lectures, and reading with a preceptor (?), will seldom be behind, and in many instances is ahead of him. A well-meaning gentleman, who, until three years ago, handled the plough with adept hand, and, as he himself informed me, with great seeming satisfaction, "couldn't neither read nor write at that time," has just put up his name, with the cabalistic M.D. after it, on the house next to mine. He showed me a diploma, certifying that J. M. had been granted the degree of doctor in medicine for numerous sufficient reasons, by the Faculty of the Medical Department of the University of Round-Holed Corners. The diploma was in Latin, such as Terence, or any *late* Latin author would have rejoiced to produce. J. M. confessed to me, under his breath, that his early education having been

neglected—rather superfluous information—he had never been able to learn just how much he did know. This I interpreted as a modest request that he would like to have the document translated. That I did; and though neither English nor American was his language, but the beautiful pastoral dialect spoken in the Far-Down East, he seemed to understand. Thenceforth, whenever I passed his window, he was seen wrapped in ecstasy, gazing intently at the diploma as at an object of devotion, with a Latin dictionary which I had lent him in his hand. At last he mastered the words for himself, and rushing in to me, with the elegantly framed parchment in his hand, he pointed to it in triumph and said:

"Wall neow, I know all about it, an I'm a doctor neow, jes like yeow; ain't I?"

This man is beating me all to pieces in practice.

"We was both docteurs," said a farmer, "an' won docteur don't know more'n anuther."

I am aware that many will impute the causes of my non-success to myself, and will have it so, say what I may. But I cannot subscribe to their opinion, savor as my opposition will of self-sufficiency. The best proof that I am right is found in my knowledge of the career of no less than ten first-rate men, who likewise went through hospitals. I have been at the pains to consult these gentlemen, and, though my lucky brethren may find in the substantial agreement of the unsuccessful ones' views a point for joking about misery loving company and foxes losing tails, I beg to suggest that these views are the product of very bitter experience, and at least worthy of attention.

I would like to ask those favored gentlemen who lecture on the needs of this great and growing country for more doctors, if they were ever at a place in its limits where there was a deficiency of the article? "A deficiency of the good article." Ah! very well; but is it not just this wholesale making of doctors by the medical schools and their professors which brings about this state of things? What would you have? Surely it is the interest of the schools to have as many students as possible, and the interest of each professor to graduate as many of his class as he can. One of the colleges in New York turned out a man as M.D. who, to my personal knowledge, could not tell the branches of the aortic arch, and whose examination in other departments than anatomy was proportionally brilliant. It is time some one should speak out, and, as one who knows, I arraign our medical colleges as opening the ranks of the profession to a body of men who, as a class, are absurdly incapable, and, in consideration of the interests of life and death to be committed to their care, criminally incapable. I have known of the leading medical college of New York, some years since, graduating a man who never soiled his hands in the dissecting-room, never touched a body, and whose reading comprised only that labor-saving machine, Neill and Smith's Compendium; that is, he was never known to have any other medical work, and if he did, it was certain that N. and S. taught him all he knew. This man got a certificate of study from a doctor in whose office the student had never entered, and systematically "cut" lectures. Of course this bogus doctor, as bogus as the possessor of any bought diploma, this "*virum probum*," had an ignoble and brief career. Not at all. The time that other and more conscientious men gave to study, he gave to developing the qualities vulgarly known as "brass" and "check;" to influencing politicians successfully in his favor, and to drawing up "*Rules to be Observed during Treatment*;" and to-day his income is not less than ten thousand dollars yearly. Can we

wonder that the community favors quacks? Nay, I have no hesitation in saying, and I say it boldly, that I would prefer at any time the services of an intelligent "quack" to such a "regular" doctor. I know that parallel cases exist in all the institutions in the great cities, and if this be the case there, what must be the depth of knowledge of the country-school graduate, who is from a free school, from where the "professors" go out in the highways and hedges and compel students to come in?

The sublime trust with which some members of the profession speak of the general acceptance of a medical college degree as an educational guarantee is a patent instance of faith without works. What nonsense the professor utters, who says to the President, in the face of an admiring audience, smiling "graduates," and after music by the band, "These candidates have shown by their examinations," etc. A large proportion have shown great ignorance by their examinations; have copied stale text-books to construct that wonderful literary production, the "Thesis;" have given certificates of three years' study, and of a moral character, from one whom they may have seen once in their lives; and have attended mythical lectures. How does the faculty know that candidates have attended two courses of lectures? The faculty is sure of one thing, and you may be sure of it. The candidates have shown, by handing over greenbacks, that they have *paid* for the lectures, which they may have never heard; for dissection, which they may have never prosecuted; and for graduation, which they are sure to get. I know this picture of a first-class medical college is not the received one. I only know it to be true. Why! you are requiring Spartan virtue of men when you expect them to stickle about how much a man knows, when he has paid for what he expects to get, and when "putting him through" is the condition of getting to more pay for similar easy graduation. There is no doubt of it. Our medical colleges are run with one great object in view—to make money for the professors, and the competition between them is fierce, not as to the quality, but the quantity of the material they turn out.

When I mention these facts to the nabobs of the profession, I do not find them denied, but it is usually said, "Oh! yes; but the inferior men drop off, and if a man really sets about to learn something for himself, he must distance the ordinary run of new graduates in a short time." For the reasons gone over I believe this view to be all fiction. It is useless to expect the laity to inquire whether a man has had hospital experience, and has studied abroad. If the absurd "ethics" of the profession permitted a man to tell people his qualifications in public print, it would be different. This exclusion from advertising I deem sufficient answer to those who contend that medicine is no worse than any other business or profession, law perhaps excepted. What earthly objection is there to advertising? "Honor, dignity of the profession," says the great and wealthy Dr. Blank. Of course, Dr. Blank, you don't need it; but how about us poor devils? What reason is there for my not letting people know I have had special opportunity to study eye diseases, or fractures, or what not? We stand by, and let charlatans reap all the benefit of this great means of success. But why let medical colleges advertise?

DIPLOMA.

DR. J. H. POOLEY, of Yonkers, has been appointed Professor of Surgery in the Starling Medical College, Ohio.

HOMŒOPATHY IN THE MICHIGAN UNIVERSITY.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Having read with interest in a recent number of your valuable journal Prof. E. S. Dunster's statement in reference to the action of the Michigan Legislature and the Board of Regents, and also with regard to the status of the faculties of medicine in the University, I beg to submit another view, which I believe to be not only more correct, but less calculated to mislead the minds of your readers in regard to the degree of union, or fusion, of the faculties in the Homœopathic and Allopathic Colleges in the Medical Department.

The regents, in adopting the resolution "That a Homœopathic College be established," of course implied that a definite curriculum of studies should be pursued, to qualify the homœopathic student for the honor of the degree of doctor of homœopathic medicine. This curriculum, it was enacted, should be equal to that required of the student of the "old school" in the department. In conformity with established usage this degree should be conferred by the regents only, upon the recommendation of the faculty of the Homœopathic College. Now, as the faculty of any college consists of the teachers specially employed to qualify and recommend the candidate for the degree, it will at once be seen that the professors of anatomy, of physiology, surgery, chemistry, and obstetrics, of the "old school," must be united practically with the newly appointed professors of homœopathic practice and materia medica to constitute such a faculty. The merely technical dodge, that they are by appointment members of another faculty, will not convince any one to the contrary, in opposition to this single prominent, practical fact.

The professors of the "old school," therefore, bear the same relation as teachers, examiners, and final judges of qualifications for the degree in homœopathy as they do to the class of candidates for honors in the regular college. By another technical dodge, the bearing of which will readily be seen, the regents have excused the faculty from affixing their signatures to the diplomas by abolishing that time-honored custom, which has hitherto existed in all the departments of the University.

I think, therefore, it will be conceded by every one who prefers facts to mere subterfuges, that as practically more than two-thirds of the faculty of the so-called College of Homœopathy are also members of the faculty of the college of regular medicine, that the fusion of the faculties of the department of medicine is nearly complete; and further, that of whatever of merit or demerit may in the estimation of the regular profession attach to such a union for the promulgation of the dogmas of homœopathy, the majority of the faculty of the regular school will be entitled to a full share.

Very respectfully,

A. SAGER, M.D.

ANN ARBOR, Aug. 17th, 1875.

UNIVERSITY COLLEGE HOSPITAL OF LONDON.—The vacancies recently caused by the promotion of Dr. Ringer and Mr. Christopher Heath, have been filled up by the appointment of Dr. G. Vivian Poore, of Charing-Cross Hospital, to be Assistant Physician, and Mr. Arthur E. J. Baker, Surgeon to the City of Dublin Hospital, to be Assistant Surgeon.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from August 22d, 1875, to August 28th, 1875.

WILLIAMS, J. W., Assistant Surgeon.—Granted leave of absence for one month, with permission to apply for an extension of two months. S. O. 159, Department of Dakota, August 17, 1875.

HALL, J. D., Assistant Surgeon.—When relieved by Assistant Surgeon Brown, to comply with par. 3, S. O. 135, c. s., A. G. O.

BROWN, P. R., Assistant Surgeon.—Assigned to duty at Fort Shaw, M. T. S. O. 164, c. s., Department of Dakota.

NAVY.

A BOARD of Naval Surgeons, to consist of Medical Inspector A. L. Gihon, President, Medical Inspector A. C. Gorgas, and Acting Assistant Surgeon J. J. Sowerby, has been ordered to meet at Annapolis for the examination of candidates for appointment as Cadet Engineers and Midshipmen at the Naval Academy.

Medical Items and News.

DISTURBANCE AT THE GENERAL HOSPITAL AT GHENT.—It is reported that one of the physicians or surgeons of the General Hospital in Ghent, in consequence of some dispute, the cause of which is not mentioned, called out to the young gentlemen, "You are all fools" (cretins). Thereupon they, being deeply offended, wrote to the hospital committee demanding an apology, and stating that, in the event of a refusal, they would adopt decisive measures. The committee answered that the letter was rude and threatening, and that no notice would be taken of it. Thereupon the students announced that they would quit the hospital; and, in order to avoid any detriment to the patients, they would stay for three days to allow them to obtain substitutes. After this interval the whole of them vacated the hospital, and the committee at once applied to the other students, but no one would accept the advantageous terms that were offered. The practitioners of the town were afterwards applied to, but only four responded, which is a small number to take the place of between twenty-five and thirty students.

AN ENGLISH COUNTY COURT VERDICT.—The *Lancet* has a communication to this effect:

I was called to attend Mrs. N— in her confinement at seven o'clock in the morning. I remained two hours. During that time she made very little progress. As it was a case of natural labor, and all was right, I thought I might safely leave her for half an hour, as I lived within three minutes' walk from the house. When I returned the child was born. I tied the cord, removed the placenta, stopped two hours, as she threatened to have hemorrhage, and attended nine days. At the end of that period she paid half the fee, promising the rest in a few days. I summoned for the remainder. The judge nonsuited, because I was not there when the child was born.

Yours, &c.,

A. W.

LONDON, July, 1875.

DR. F. D. LENTE's health having been impaired by hard work, he proposes to spend the coming winter in Palatka, Florida.

INSTRUCTION IN PSYCHOLOGICAL MEDICINE.—The Royal College of Physicians of London have adopted the resolution "That the registrar prepare and submit a regulation to the College that students who wish to qualify for the examination for the membership or license of the College may substitute, if they so desire, a three months' course of clinical instruction in the wards of a lunatic asylum for the same period of attendance in the wards of a general hospital."

ABERDEEN UNIVERSITY.—Dr. Stevenson, of Edinburgh, succeeds to the Chair of Midwifery and Diseases of Women and Children, in the University at Aberdeen, Scotland, left vacant by the death of Dr. Inglis.

THE GRAPE-JUST.—M. Dumas, the discoverer of the application of sulpho-carbonates to the destruction of the phylloxera, appears to have met with two serious competitors for the 300,000 francs prize, in the persons of MM. Ph. Zoeller and A. Grote, of Vienna. They propose xanthate of potash dissolved in water. This substance is cheaper than the sulpho-carbonate, and, like it, evolves sulphuret of carbon, deleterious to the insect, but with the advantage that it does not yield hydro-sulphuric acid, which is injurious to the vine.

THE SYSTEM OF DRAINAGE OF LONDON.—The *Lancet*, of August 14th, says that after a labor of sixteen years, and the expenditure of more than four millions of pounds sterling, the undertaking known as the metropolitan main drainage system has been brought to completion. The whole of the sewage of more than four millions of people, living on an area of over 117 square miles, is now diverted from the Thames, near London, and discharged at Barker, near Crossness, fourteen miles below London bridge, into the river at high water, in order that the ebbing tide may carry it out to sea. Until the opening of the western pumping station, at Pimlico, on the 5th of August, the sewage of an area of nearly fifteen square miles of West London, including Chelsea, Fulham, Brompton, Kensington, Shepherdsbush, Wormwood-scrubs, Notting-hill, and Hammersmith, was discharged into the Thames at Cremorne. The last portion of the metropolitan sewage has now been diverted from this part of the Thames, is now lifted to the height of eighteen feet, and then finds its way into the low-level sewer, which carries it to the Abbey Mills pumping station. So recently as 1815 a penalty was incurred by discharging house drainage into the sewers, which were only intended for surface drainage. Up to that period the cess-pool system remained supreme in London. The nuisance of this system, however, became so intolerable that in 1847 a law was passed making cess-pools illegal, and requiring all householders to do what was a penal offence before 1815—that is, to drain into the sewers. In the meantime, however, the Thames was becoming a gigantic open sewer, and three warnings, in the shape of cholera epidemics in 1833, 1849, and 1854, combined with the powerful incentive to action in the matter produced by the effluvium of the Thames upon the legislators in the Houses of Parliament, led to the inauguration of the metropolitan main drainage system in 1859. The system is now complete, but the sixteen years during which it has been in progress have passed without the solution of the problem how to utilize this vast amount of sewage now cast into the sea. This still remains to be solved.

THE N. W. Medical and Surgical Society should have been credited with the resolutions on the Presbyterian Hospital, instead of the Medical Board of the N. W. Dispensary.

Original Lectures.

THE GENERAL MANAGEMENT OF FRACTURES.

A LECTURE DELIVERED AT BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK,

By A. B. CROSBY, M.D.,

NEW YORK.

[Phonographically reported for THE MEDICAL RECORD.]

GENTLEMEN:—I shall occupy the hour to-day in considering some clinical points with reference to the management of fractures. I do not mean that I am to enter into a discussion of the subject of the treatment of fractures, but I simply wish to present for your consideration a few points, the neglect of which is likely to prove disastrous to the patient in many instances, and the observation of which is likely to inure to his benefit. I may with propriety first allude to the signs indicating the presence of a fracture, and these are (1) deformity, (2) preternatural mobility, and (3) crepitus. Now, the deformity which may exist in a given fracture may consist of shortening alone, or this may be combined with distortion, which may be even so great that the portion of the limb below the point of fracture may lie at a right angle to the portion above the point of fracture. When you come to examine a limb, then, in which a fracture is supposed to be present, you will first notice that the parts present an unnatural appearance; that there is a deformity.

Preternatural mobility is not subjective, but objective; that is, the patient cannot move the limb himself, but the surgeon can move it in such a manner as to show where the point of motion exists, and so determine precisely at what point the fracture has taken place. Such an examination enables us to determine that there is a new point of mobility, and that the patient cannot himself move the limb as well as he was able to do previous to the receipt of the injury. It not infrequently happens that any effort on the part of the surgeon to move the limb, for the purpose of determining the point of fracture, causes a spasmodic contraction of the muscles, which gives rise to such pain that if he would make the answer to this question positive, he will be obliged to conduct his examination while the patient is under the influence of an anæsthetic.

The sensation of crepitus is objective, therefore obtained by the surgeon, and is produced by either rubbing the broken surfaces of bone together, or holding one in a fixed position and rubbing the other against it. Crepitus may be distinguished in two ways; first, by the sense of hearing; second, by the sense of touch. It can be detected by the sense of hearing when the bones are situated close to the surface of the limb, as in the tibia, but when the bone is covered to a considerable depth by the surrounding soft parts, as in the femur, crepitus is more commonly detected by the sense of touch.

Now, men do not ordinarily get fractures under circumstances specially suited to the convenience of the surgeon, but they are quite as frequently at some distance from their homes, or the place where they are to receive appropriate permanent treatment. The first question, then, for the surgeon to decide will be, can the patient be carried home, and, if so, how is it to be done? If the fracture involves an upper extremity, the limb can usually be dressed according to some approved plan, and the patient permitted to walk or ride

home according to his convenience. If fracture of one or more of the ribs has taken place you can support them in a position of comparative immobility by means of adhesive plaster applied in broad strips around the chest over the seat of fracture, and the support thus given will enable the patient to reach his home much more comfortably than he would otherwise be able to do. Usually persons suffering from fractured ribs prefer to walk rather than to ride, and in general you will see them walking with the greatest ease, with a sort of preternatural solemnity and rigidity of the body, lest motion occur at the seat of fracture. If the fracture involves a lower extremity or the spine, your patient will be unable to help himself; in other words, he must be carried to the place where he is to receive the attention and dressings necessary to retain the bones in the proper position for union to take place. The means for carrying a patient under such circumstances will usually consist of some sort of improvised stretcher, such as I described to you at our last meeting, and need not be again described in this connection.

Now, the shortening which occurs in fracture is the result of muscular contraction, and such contraction, if permitted to go on unrestrained, will serve to drive the ends of the broken fragments of bone into the soft parts. The injury naturally inflicted in this manner will act as a stimulus to excite still further spasmodic contraction of the muscles, and the result is, not only pain to the patient, but irritation of the soft parts, which may be followed by an inflammation that will unfavorably affect the final union of the fragments of bone. The first indication, then, in the treatment of a fracture is to coaptate the fragments, and then retain them in position. This can be done temporarily for the relief of the suffering of the patient, and avoiding injury to the muscles or other tissues, if you will yourself, or have an assistant, seize the foot or ankle, and draw the limb down, and hold the muscles quiet by such extension. For in this manner the irregular muscular contraction will be overcome. There is, therefore, a great advantage in having an attendant, who shall hold the ankle or foot in his hand while the patient is upon the stretcher, and who shall maintain sufficient extension to overcome muscular contraction, and so keep the parts quiet. The surgeon, however, may relieve himself or his assistant in this respect, to a great extent, by giving some firm, equable, lateral support to the fragments themselves. This can be done by taking a shingle, pieces of a cigar-box, or pieces of heavy pasteboard—cover them with cloth if you choose—and then secure two or more of these pieces to the sides of the limb by means of strips of cloth or a roller bandage. In the country you may very likely find stiff rye or wheat straw, and by taking fifteen or twenty of these straws, and tying them together, so as to make a little bundle or junk, you can very soon extemporize a most admirable lateral support for a fractured bone. Several of these straw junks can be placed lengthwise of the limb, sufficient to surround it, and then secured by strips of cloth or a roller bandage. Before applying any lateral support whatever, it is important to have an assistant make sufficient extension to overcome all muscular contraction, and then these supports can be applied, and secured even above the seat of fracture. In this manner the tendency to muscular contraction can be reduced to its minimum.

For, as you are well aware, muscular contraction causes the fibres of a muscle to shorten, and proportionately increases the transverse diameter of its belly, and a firm, equal lateral pressure prevents this increase

in transverse diameter, therefore prevents muscular contraction. It is in this manner, then, that you can prevent such contraction which gives rise to displacement of the fragments, and consequent injury of the soft parts.

If the patient is to be carried farther than can be consistently done on a stretcher, a bed may be placed in the bottom of a wagon and the patient laid upon that. He may lie completely in the horizontal position or half inclined upon the side, while the limb should be supported by some attendant, who, at the same time, should maintain a moderate amount of extension.

Your patient having reached his home, the question arises, when is the permanent dressing to be applied? or, in other words, *when is the broken bone to be set?* I am surprised that some surgeons have been found who advocate leaving a fracture practically without dressing for some days, upon the theory that the material necessary for the repair of a broken bone is not thrown out until seven to ten days following the occurrence of the injury, and therefore that it is a matter of indifference whether the dressing is applied before that time or not. Such a theory is exceedingly pernicious. The sooner a fracture is dressed the better it is for the patient; for, if you leave it subject to irregular muscular contraction, there will be more or less laceration of the soft parts by the ends of the fragments, irritation will be produced, and undue inflammation will be much more likely to be present. It seems to me that the question is settled beyond discussion, and that the surgeon who neglects to reduce a fracture as soon as possible after it has been received, and secure it in position by proper dressings, is certainly guilty of a misdemeanor, if not of actual crime.

ARRANGING THE BED.

A patient who has sustained a fracture of the thigh or spine cannot be treated successfully upon every bed you may happen to find in the house. In the country, if you ask for the best bed to place the patient upon, you will very likely have shown to you a nice feather bed, mountain-high, in which, if you place your patient, you will find that you have "plunged him in a gulf of dark despair." Such a bed is soft and delicious enough for certain purposes, provided it is not too highly scented with the aroma of the past, as it is very apt to be; but you will find that you cannot successfully treat a fracture while your patient is surrounded by any such mass of feathers.

The only bed upon which a fracture can be successfully treated is one which affords a dead level surface. Now when you come to practise in the country you will find that the bedsteads frequently are fastened together with a cord, and almost invariably this will be found to be loose, so that every move which is made upon the bed will give rise to notes which are anything but harmonious to a finely trained musical ear. The first thing, then, that I usually found myself obliged to do in the country was to obtain a hammer and pin and a bed-wrench, and "cord up" the bedstead. I was then accustomed to have pieces of light, dry board sawed of such length that they would drop between the rails of the bedstead and rest upon the cord, so that it was in this way floored over with boards, which furnished a level surface. The common slat bedstead now in such extensive use answers a very good purpose, provided the slats are sufficiently close together to give a flat, unyielding surface when the patient is laid upon them. Upon such a surface there should be placed some kind of a mattress. A

couple of hair mattresses make one of the very best of beds upon which to treat a fracture.

The ordinary excelsior mattress may be used, and over this one or two comfortables can be placed, which will render it somewhat more agreeable for the patient, but none of these coverings should be sufficiently thick and soft to permit the body of the patient to imbed itself into the surface upon which it rests.

Other things being equal, a person can lie longer, without suffering serious inconvenience, upon a hard than upon a soft bed. If the patient is suffering from a fracture of the spine, or has suffered from any injury which is accompanied with great loss of power, and will necessitate the parts below to be subjected to persistent pressure, we are very apt to have the ordinary results which follow long-continued pressure and loss of vitality, namely, bedsores. It is not safe, therefore, to attempt the treatment of a patient who has received a fracture or other serious injury of the spine upon an ordinary bed. For this purpose the best bed that can be employed is the air or water bed. This consists of an india-rubber bag or flattened sac of the requisite dimensions, which can be filled with air or water, whichever you may prefer to employ. In either case the sac should be only moderately distended, that is, it should be left a little yielding, so that, when covered with a blanket, it will yield just enough to pressure to fit the back, or whatever part of the body may come in contact with it, perfectly and equally throughout; for perfectly equable pressure never resulted in a bedsore. It is only persistent unequal pressure upon prominent points which is likely to give rise to bedsores, and if the same persons, in most cases, who have bedsores, had been as persistently in one position upon an air or water bed, such sores would not have occurred.

MANAGING THE DEJECTIONS.

The management of the dejections from a person who is confined to the bed with a fracture sometimes becomes a serious matter. It is for this reason that many surgeons, when treating a fracture of the lower extremity, have one thick mattress, in the central portion of which is a round or square opening, and in the floor of the bedstead a trap-door that can be opened or closed at pleasure from the under side. The cavity in the mattress is filled with a cushion sufficiently thick so that no depression is left in the surface when it is in place, and when the patient wishes to have a movement from the bowels it falls out as the trap-door is unfastened. With such a convenience he may have a dejection in comparative peace. It is usually necessary to have a urinal independent of the vessel which is used beneath this opening in the bed, and the greatest care must be exercised in keeping the mattress around the opening, and also the patient's clothes, perfectly dry and clean.

It does not always happen, however, that you can have such a mattress and the arrangement I have just alluded to, and the next best arrangement that can be employed is the ordinary dust-pan. Cover such a pan with a folded sheet, or towel, having previously pushed a towel before it for the purpose of protecting the dressings upon the thigh, and then raising up the sound leg the thin edge of the dust-pan can be easily carried well under the body of the patient and receive the dejection. If the discharge is so copious as to be likely to soil the clothing, the patient should arrest it, the pan be removed, a fresh sheet applied, and then replaced. The dust-pan can be placed beneath the patient much easier than the bed-pan, as, if the latter is used, you will be much more likely to disturb the frac-

ture, while the former answers a most admirable purpose.

I have already supposed that you have got your patient home, and into bed, and now I wish to speak of a few points with reference to the permanent dressings that are to be applied. In the first place, preparatory to this, the limb had better be washed. It may seem superfluous to you that I should make this remark, for it is to be expected that any neat surgeon would see to this at once; but I can assure you that although expected, it is not always realized, and limbs are fractured and dressed, which are not unusually clean, and as it is to be shut in for some time the amount of filth confined in this way may be very great. It is desirable, therefore, to have the limb first washed thoroughly with soap-suds. If there is any extension to be made, it should be done by means of adhesive plaster applied to the sides of the limb and secured by a roller-bandage. There is one precaution that should be always observed before applying the plaster, and that is, to shave the limb. This may seem to you like another insignificant suggestion, but you will find it very valuable, and if you omit its observance you may be necessitated to undo the entire dressing which otherwise is well applied.

BANDAGES.

The question of bandages is one upon which, first and last, there has been a great diversity of opinion. The two forms of bandage in common use are the ordinary roller bandage and the bandage of Scultetus. Now the question arises, when to use a bandage, and where to use a bandage; and these are very important.

I think it may be laid down as a law that the roller bandage never should be carried around the limb over the seat of fracture, unless you are applying some permanent dressing.

The reason for this rule is that if you are using a movable dressing, one which is to be removed to enable you to get at the surface of the limb over the seat of the fracture, you cannot do it without the greatest inconvenience if you employ the roller bandage.

The roller bandage, however, should be applied usually from the tips of the extremities up over the limb for a certain distance. For instance, in case of fracture of the forearm, the bandage should be applied over the fingers, hand, and to the wrist, but should never be carried over the forearm. In this special instance there is an extra reason for this, to which it is well to direct your attention, and this is, such bandaging will destroy the parallelism of the radius and ulna, and secure union with the fragments in a position to destroy all supination and pronation, and therefore, to a very great extent, the future usefulness of the limb. The theory in dressing these fractures you are already familiar with. With fracture of the humerus, the roller bandage may be carried over the forearm to the elbow, for the purpose of preventing the occurrence of swelling below the seat of fracture after the permanent dressings have been applied. With reference to the lower extremity, the same principle holds good; and with fracture of the thigh, you will be obliged to bandage the foot, ankle, and leg to the knee, and then leave the seat of fracture uncovered by this form of bandage.

In fractures of the lower extremity, however, there is no objection to applying over the seat of fracture the bandage of Scultetus, which is the most beautiful bandage ever devised, and the one that affords the most equable compression. This bandage can be applied and laid over the limb without disturbing the

line of fracture, and that cannot be done with the common roller bandage.

The bandage of Scultetus is made in the following manner: First, tear a strip of old cloth about two and one half inches wide and as long as the part you desire to cover. Next tear several strips, about the same width and long enough to go once and a half around the thigh, or whatever limb you may be treating. Now, having laid the first strip in one direction, take one of the strips which are to go around the limb, and place it across the first strip at a right angle, the middle of the latter strip corresponding to the middle line of the former. A second transverse strip is then laid upon the first, overlapping it by one-half its width, and so you will go on until the strip, representing the length of the part to be covered, is itself covered by these transverse pieces. These pieces should then be fastened by two rows of stitches at the point where they intersect each other. The bandage is then complete and is applied to the posterior surface of the limb with the single strip running lengthwise. Then beginning at the lower strip one end is passed around the limb, while the other is made to overlap it, and the second strip follows this, and so on until the last one is turned, which is to be fastened with a pin, and the entire bandage is secured. When you wish to examine the limb, all that is necessary to do is to remove the outside splints, unfasten the upper strip, and turning back one end after another you soon reach the bare surface. Now by such palpation as is necessary you can determine whether or not the fragments are being retained in proper relation with each other.

There is one caution which should always be borne in mind by the surgeon when dressing a fracture, and that is, *all* dressings, in order to be borne and to be useful, must compress the limb in all places equally. If you are to apply a bandage over an extremity up to near the seat of fracture, it must be applied in such a manner as will give a perfectly equable and firm pressure. If there is any difference to be made, it should be the firmest at the tip of the extremity and less firm as you go up the limb; but as a rule, the more equable the pressure the better it will be borne, and the better will be the result.

You are usually instructed in the books that the primary dressing applied to a fracture should be a loose dressing, but if you see the limb soon after the accident has occurred, and apply a firm dressing equally around the seat of fracture, and then cover it with a splint and other dressings, you will not have swelling. Where swelling occurs it is almost invariably due to the fact that the dressing has not been sufficiently equable, that is, the pressure upon the limb has been unequal, compressing it firmly at one point and very much less firmly at another.

After dressing a fracture, if the patient complains of pain, and you examine and find the extremities discolored and cold, there is only one inference to be made, and that is, that the circulation of the limb has been interfered with, and that it is due to the fact that the dressing makes unequal and too firm compression of the limb. Under such circumstances it is worse than a crime for the surgeon to allow the dressing to remain unchanged, and upon this point I cannot insist too strongly. It should be undone at once.

There is another point, and that is, after fracture there is liable to be a certain amount of spasmodic jerking of the muscles, which gives the patient more or less annoyance, and in some instances a good deal of pain.

This is usually due to the fact that the dressings do not give the muscles sufficiently equable pressure.

The only splints with which you can treat a fracture well are those which can be moulded so as to perfectly fit the limb over the entire surface, and such a splint can be applied with considerable firmness, and in that manner overcome all unequal muscular contraction. In some cases, when the patient is nervous and bears the pain badly, it may be necessary to resort to anodynes and nervines, until the habit is somewhat acquired of quietly yielding to the demands of the broken limb. But in general, if the dressings are equably applied, but little inconvenience will be experienced in this direction.

GENERAL DETAILS.

In addition to these cautions with regard to bandages, I may say a few words with reference to some points in the general management of the patient suffering from fracture. You will find that when a patient who has been leading an active life becomes suddenly confined to the bed, the bowels and bladder will be usually quite sluggish, and you will be obliged to solicit their action. At the end of two or three days, therefore, after the fracture has occurred, it is well to administer a simple saline, and so secure a movement. This is a matter of considerable importance, and should never be lost sight of. The same thing may be said with regard to voiding the urine. Some persons find it exceedingly difficult to empty the bladder while lying in a horizontal position, and it is quite necessary that you should use some precaution in this respect. It may be well for you to instruct some intelligent attendant how to use the catheter, so that in case the patient is unable to empty the bladder, he can be relieved without unnecessary delay, and without calling for your assistance, perhaps in the night.

There are some persons who are entirely ignorant of the sensations and pain produced by over-distention of the bladder, and will have the idea that all their peculiar feelings depend upon the fracture from which they are suffering. It is necessary, therefore, that your inquiries should turn directly towards ascertaining the condition of the patient in this respect.

DIET.

I believe that the diet of a patient with a fracture is quite as important as that of a patient with a fever.

The person who is suffering from a fracture must have nutriment, not merely sufficient to repair the ordinary waste that is going on in the body, but he must have a little surplus of vitality added, for the repair of the fracture. The food should be simple, but thoroughly nutritious. More persons are thrown into a surgical fever from starvation than from a generous supply of simple but nutritious food.

STIMULANTS.

The question of stimulants is one which has an important bearing. There may be a certain amount of shock produced by the accident, perhaps collapse, and the stimulants are to be employed until reaction is well established, after which it is probably better that they should be discontinued.

I refer especially, however, to that class of patients who have been accustomed to the use of stimulants prior to receiving the fracture.

It is well to cure the drunkard of his habit, but it is not well to commence the temperance reform with a drunkard who has just received a fracture. I have seen the experiment when inebriates have been perforce rendered temperance men during the treatment of a fracture, and I have more frequently seen ununited

fractures in this class of persons than any others. If the person has been in the habit of indulging in alcohol, you should not attempt to force temperance upon him during the treatment of a fracture. You may perhaps diminish the amount, but the patient should receive a certain amount of stimulation daily; and it is not only comforting to the patient, but it may be the sole condition upon which you will obtain a successful union of the fractured bones.

There are certain other questions to which I will direct your attention at our next meeting.

Original Communications.

ON THE TREATMENT OF PHAGEDENIC GANGRENOUS VENEREAL SORES.

By D. B. SIMMONS, M.D.,

CHIEF SURGEON OF THE KEN HOSPITAL, YOKOHAMA, JAPAN.

FEW who have had any considerable private or hospital practice are not acquainted with the difficulties often experienced in arresting the destructive progress of what are known as phagedenic gangrenous venereal sores.

Within the last two years several cases which will admit of this classification have come into the hospital for treatment. The hot iron, nitric, chromic, and carbolic acids were all tried in turn, as well as "Ricord's born enemy of phagedena," with what we believe to be the average rate of success.

The last four cases, and one especially, which we shall refer to, were almost entirely treated, however, by, if not a new process, one which was productive of such satisfactory results as to warrant us in earnestly recommending its trial. *This consists in the continuous immersion of the diseased part in hot or warm water.* The case referred to had been treated, before falling into our hands, by the usual means for nearly two weeks, and, though not progressing so rapidly as at first, was still advancing. Both labia, minora and majora, the fourchette, clitoris, and portions of the urethra had disappeared, and all the region occupied by the external organs of generation had been converted into an immense irregular cavity, discharging an unhealthy, sanious, and very fetid pus. The patient was also suffering much pain, especially if the parts became in the least dry. A sitz-bath of the ordinary size and form is what is required. In this is placed a cushion, or large bathing-sponge, to render more tolerant the long-continued position in the tub, required for obtaining the more satisfactory results. In the case referred to, the matter seemed to be increased by the use of the bath for thirty-six hours, when it began to change in character. Instead of the sanguino-serous pus which was discharged from it before, it had assumed a more healthy, "laudable" form. The ragged edges sloughed off, and their darkened or purple color presented a bleached-out appearance. From this time the progress of the disease appeared to have been arrested.

Through the dirty gray slough at the bottom granulations began to appear, and the healing up of the part, as far as the extensive loss of substance would admit, was completed in two or three weeks. As uncomfortable as the position was, the patient would not remain out of the bath for a moment longer than necessary, on account of the great relief it afforded from the burning, smarting pain.

We found, after the change had commenced for the better, that it was not necessary to keep the patient so continuously in the bath, but only on alternate hours. In the interval, iodoform was sprinkled freely over the part. It is our opinion that the destructive agency is to be found in the peculiar or specific character of the discharge, and that the water simply removes or dilutes it, so as to destroy its action, the same as it would with a caustic. We do not see why this explanation is not as true and satisfactory as that the matter from a soft chancre has specific qualities, and is capable of reproducing itself, under favorable circumstances, to almost any extent.

A very bad case of multiple chancres in a female, of an inflammatory type, was treated by us in the same manner, with the same satisfactory results, about the same time.

In the male, when the organ is sufficiently large or long, we have found its immersion in a tumbler or cup of water answered the same purpose.

We now adopt this plan in the treatment of all soft chancres that are troublesome, and are satisfied that if it is properly carried out they may often be cut materially short in their duration.

All are acquainted with the suddenness with which soft chancres often get well after long and varied modes of treatment. We believe this to be consequent upon a change in the character of the discharge, or in its irritating corrosive action, which allows of the natural healing of the wound. The same is practically effected by the dilution or removal of it by the water.

Irrigation, we have no doubt, would answer the same purpose, and could be arranged so as to subject the patient to far less inconvenience and discomfort.

We think, however, that the water should be at as high a temperature as possible in either case.

ON THE EXISTENCE OR NON-EXISTENCE OF OZONE.

By T. C. STEARNS,

ROCKFORD, ILL.

MEETING with the assertion that ozone is probably produced by the bleaching of solutions of permanganate of potassium by organic compounds (Brande and Taylor, p. 113), and knowing that medical men generally suppose ozone to be the product of the reaction between oxalic acid and permanganate of potass, my attention was called to the subject by the fact that, theoretically, carbonic oxides [C.O₂] is the product of this change according to the following equation—

Proceedings were then instituted to determine the truth experimentally.

A tall glass bottle was fitted with a cork admitting a thistle tube, and two other tubes, each connected with glass vessels containing lime water, the one through which the air contained in the apparatus was forced to deprive it of its carbonic oxide, and the other for the purpose of testing the air in the apparatus after the reaction had taken place. A solution of permanganate potassium was now poured through the thistle tube into the large bottle, and immediately

after, a solution of oxalic acid. As soon as the reaction had taken place, as indicated by the decoloration of the mixture, the air above it was forced (by the filling of the bottle with water through the thistle tube) through the last bottle of lime-water, when a plentiful deposit of carbonate of lime was seen. Interest being aroused by the above, we concluded to continue our experiments with the various modes of producing ozone.

In the bottom of the tall glass bottle a few crystals of permanganate of potassium were placed, and covered with sulphuric acid; a test-paper (saturated with potass. iodide and starch) hung in the tube was instantly colored by the decomposition of the iodide and production of the blue iodide of starch. As we had before discovered that acid fumes will produce the reaction, even where no ozone exists, as over the fumes of hydrochloric acid, we made the following test to ascertain whether the acid fumes or the ozone produced the change of color in the test-paper: The cork of the bottle was fitted with one perforation for a thistle tube, and another for a tube connected with a bottle containing an alkaline solution. The reaction between the permanganate and the sulphuric acid was again caused to take place, the air in the bottle forced out as before, and after passing through the alkaline solution, *would not give reaction for ozone.* The experiment for the production of ozone, by the slow combustion of ether, conducted by dropping a hot glass rod into a beaker containing ether, was then made, and as usually performed gave the reaction for ozone, but as soon as the "acid fumes" were removed by pressing the atmosphere contained in the beaker through an alkaline solution, *no reaction took place* when the test-paper was held in its current. While with only the above experiments before us we are not warranted in asserting that ozone does not exist, they point forcibly to this conclusion; and were we to adopt it we should not be alone, for the existence of ozone has been denied by some chemists and numerous observers, among the latter of whom we may place Dr. J. F. Baldwin, who in an admirable article on "The Relation of Ozone to Disease," says: "I have tested for ozone in all kinds of weather; in the midst of fog, mist, rain, sleet, and snow; in hot weather and in cold; when the day was clear and when it was cloudy; but never—not even during a thunder-storm—have I been able to detect the slightest trace of ozone." —*Am. Jour. Med. Sci.*, Oct., 1874.

Doubts may also be reasonably entertained of the production of ozone by the electric spark, for there is certainly no need to attribute to the substance called ozone, the decomposition of the iodide in the test, for we have in the electricity itself the most potent decomposing agent known, and instead of pointing to the conclusion that ozone is produced, the fact that the jar of oxygen through which the electric spark has been passed will retain its property of decomposing the iodide for a lengthened period, should only show that the gas, like a Leyden jar, is capable of holding its electrolytic properties for a considerable time.

The author holds to the question *sub judice*, however, and intends to continue so to do until opportunity presents itself to prove certainly that ozone is produced by passing the electric spark through *pure* oxygen, as, reasoning from analogy, we suspect the presence of a compound to which we would attribute the reaction, especially as some authors assert that the production of ozone is facilitated by the presence of certain compounds, or the possibility of the power of the gas to retain its electric properties.

ROCKFORD, ILL., Aug. 10, 1875.

Reports of Hospitals.

ST LUKE'S HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

SCIRRHUS OF THE BREAST.

The point of special interest in this case related to the dressing. The breast had been removed in the usual manner, no axillary glands being involved, but since the operation the patient has suffered severely from pain in and about the wound. This pain had been very markedly relieved by applying cloths which had been wet in a solution of boracic acid.

Pieces of muslin are dipped in a saturated solution of this drug, and then dried. Before being applied they are dipped in water.

SLIGHT BURN—ABSCESS BENEATH THE PECTORAL MUSCLE.

One or two points suggested by this case may be of some practical importance. The patient, a strong, healthy man, received a very slight superficial burn upon the palmar surface of the forearm near the wrist-joint. Before this ulcer had healed a swelling made its appearance under the pectoral muscle upon the same side, which went on to suppuration. The course of treatment pursued was to delay opening the abscess until pus had come well towards the surface. This is the rule which very commonly governs the management of such cases in the hospital, unless there is present severe constitutional disturbance. Another point of interest in the case was the remoteness of the abscess from the ulcer, if so be that there was any relation between them,—without local manifestations at any point intervening.

When the abscess was emptied a deep cavity or fistulous tract was left, which had nearly closed. It had been washed out occasionally with the red wash, a remedy quite commonly employed in such cases.

WET STRAPPING.

It has been regarded as an item of some importance in the treatment of old ulcers, such as are of specific nature, found upon the lower extremities, that, if strapped, the plaster should be permitted to remain as long as possible without change. Whether the strapping meets the indication or not, cleanliness, etc., are of course, to govern the surgeon in every case. With this object in view several cases have been dressed with what have been called wet straps, which are prepared by passing strips of adhesive plaster through hot water instead of heating them in the usual manner. In these instances the water was also carbolyzed.

It seemed quite certain that the ulcers had healed more rapidly under this plan of treatment than any which had been adopted, and it was very evident that the plaster did not get loose as quick as when heated over a spirit lamp.

ECZEMA RUBRA.

A number of cases of this disease had followed facial erysipelas, and, after trying all the remedies ordinarily resorted to in the treatment of this affection without benefiting the patient, tincture iodine was painted over the entire surface. As a result, the disease was in every way aggravated for one or two days,

but when the artificial irritation subsided, the change produced in tissues by the iodine permitted the cases to go on to rapid and complete recovery.

DOUJLE COLLES' FRACTURE.

One point of interest in their case was the occurrence of this fracture in both forearms at the same time. The patient was a very fleshy woman, aged about forty-five years.

Another point of interest was the excellent results obtained by a most simple method of treatment. The fractures had been dressed with straight board splints six or eight inches long, the anterior splint reaching down to the joint, the posterior one two or three inches upon the dorsum of the hand, and then secured with a roller bandage.

The deformity was very trifling. Motion was very good in every direction and was daily improving.

In all these cases passive motion is commenced at the end of the third week.

Progress of Medical Science.

RESPIRATORY PERCUSSION.—In the last number of the *American Journal of the Medical Sciences* Dr. J. M. Da Costa describes a method of physical examination of the chest, by means of which he claims that the diagnosis of pulmonary affections may often be greatly facilitated. By respiratory percussion is meant percussion after a full inspiration or a full expiration, the breath being suspended for the moment while the examination is being made. For the sake of furnishing a standard for comparison between health and disease, a description is given of the sounds produced by respiratory percussion in the normal subject. The general effect of percussion after a full inspiration is to increase the resonance and the volume of sound, and to raise the pitch. Percussion after expiration appears to be of less practical importance, though it occasionally affords valuable information. Its effect is to diminish the resonance and lower the pitch.

The practical application of the respiratory method of percussion would appear to have a very wide range. In all chest affections, where percussion is used, the modification may be employed with advantage. It often serves to clear up a diagnosis where the ordinary physical examination leaves the case doubtful, or where the usual signs tend to mislead. Thus, in bronchitis an abundant accumulation of secretion in the air-passages may obscure the breath sounds, and even give rise to a certain degree of dullness on percussion. But if the suspected region is percussed while the breath is held, after a full inspiration, the percussion-note again becomes clear, and the doubt is removed. On the other hand, should the dullness remain unchanged after inspiration, we may infer that the pulmonary tissue has suffered damage. In acute lobar pneumonia respiratory percussion may reveal commencing resolution before any crepitation has appeared, and thus become available with respect to prognosis. In certain cases of organic heart disease, where the symptoms lead to a suspicion of tubercular complication, this method of percussion, by causing the local congestion in the lungs to disappear, will greatly assist in the diagnosis. In pleurisy, with effusion, where the fluid is at the lower part of the lung, and some doubt

exists as to whether it may not be a case of chronic pneumonia, by means of respiratory percussion the diagnosis may be rendered perfectly certain. If after a forced inspiration the percussion develops a sharply defined line between the region of dulness below and that of resonance above, it is an effusion; while if the dulness changes in part, or remains unchanged without being well-defined, we may be sure that the lung is consolidated. Again, in those cases where in connection with an effusion in the pleura we get a blowing respiration at the back, with dulness on ordinary percussion, and it is a question whether pneumonia coexists with the pleurisy, a full inspiration expands the lung tissue, if it be simply compressed or condensed, and the percussion sound becomes clear and resonant.

Obviously in phthisis, too, respiratory percussion may be made of great service in determining the existence of a deposit that is very slight in amount, or in ascertaining the degree of progress of the disease, by magnifying, as it were, the ordinary percussion signs, and by enabling us more accurately to define the limits of the disease. If both lungs are about equally affected, the presence of deposit will be denoted by the fact that respiratory percussion does not give an increased, but rather a diminished resonance, and after a forced expiration the dulness will be markedly increased. In the case of cavities the effect of a full inspiration upon the percussion sound is to change the tympanitic, cracked pot, or amphoric notes to simple dulness, together with a higher pitch and a feeling of greater resistance.

In pneumothorax respiratory percussion may be made available, it is claimed, to ascertain whether perforation between the lung and pleural cavity still remains pervious or not. If a full inspiration increases the resonance, the former is probably true; while if the resonance remains unchanged after inspiration, the aperture has closed. This, however, is not stated with complete certainty, and the necessity for further investigation is admitted. In emphysema the vesiculo-tympanitic note elicited by ordinary percussion is either not at all changed after forced inspiration, or but very slightly so in case the emphysema is not marked.

SYPHILIS OF PARENTS AS AFFECTING THE OFFSPRING.—Dr. Drysdale, in a note to *The Medical Press and Circular*, ranks himself on the side of those who hold that syphilitic children can only be born when the mother is syphilitic. This view, opposed by the authority of Trousseau, Diday, Benton, Depaul, Lee, Acton, and other writers of great note, is sustained by Notta, Berkeley, Hill, Gascoyen, Cullerier, and Owse, of Christiania, and others. Dr. Drysdale cites the following instances in support of the latter opinion: A gentleman contracted syphilis in 1850. He married some years afterwards, and now has three blooming children. Another gentleman had syphilis in 1851, and his wife contracted syphilis from him directly. She had no children. Four years later the gentleman married again, and now has a fine family of sons and daughters. Two gentlemen of his acquaintance contracted syphilis to his knowledge, and have had large families of healthy children. The case is not so where the woman has contracted syphilis. A lady contracted syphilis from her future husband, who bit her lip. He was suffering from a secondary affection of the mouth. She married, but had no children by this husband, who died in three years. A few years later the lady again married, and gave birth to a dead child. In view of such facts as he has collected, he feels warranted in assuring his male patients that if they have been

free from syphilis *some two years*, they will not have syphilitic children should they become fathers.

THE CURE OF SPLENIC LEUKEMIA BY PHOSPHORUS.—Dr. Wilson Fox has published a case in which he corroborates Dr. Broadbent's observation on the influence of phosphorus in this disease. The patient was a baker, thirty-seven years of age, and on admission to hospital showed great signs of anæmia of the mucous surfaces and nails. He was emaciated and so feeble as to be hardly able to stand without assistance. He had frequent slight rigors, was pyrexial, and sweated profusely. In the splenic region there was felt a hard resistant mass, pushing outwards the cartilages of the tenth and eleventh ribs, and reaching backwards nearly to the spine. It was smooth, not nodulated, and moved with respiration. The liver was not enlarged, nor were the superficial lymphatics, except a few in the inguinal region. The blood taken from the finger was paler than natural, and the white corpuscles were nearly twenty times their normal number, from thirty to thirty-five being seen in the field of the microscope. Besides the corpuscles, which were of two sizes, there were a large number of molecules, which were aggregated together in large masses.

At first phosphorus was given in doses of one-fiftieth of a grain three times a day. Afterwards the dose was increased to one-thirtieth of a grain at the same intervals. No other treatment was pursued at the time. Under this treatment the excess of leucocytes diminished, the weight increased, and other symptoms were ameliorated. At the end of about four months he discontinued the medicine. About a month later he had continued to improve, and his weight had risen from 124 to 147 pounds. The spleen, however, had not diminished in size, but there was an increase in the white blood-corpuscles. In this case a large number of remedies—among them quinine in large doses and iron—had been tried faithfully without success, and Dr. Fox congratulates himself that we are now possessed of a cure for at least some cases of a disease so painful and hopeless as this generally proves to be.—*The Lancet*, July 10, 1875.

NEURALGIA TREATED BY NERVE-STRETCHING.—Mr. Callender, of London, reports the case of a man who had undergone amputation of the forearm twice—the second time owing to imperfect healing and a painful condition of the stump. The second wound healed, but he was liable to attacks of pain in the stump. About seven weeks before his presenting himself to Mr. C., he struck the end of the stump, and since then the pain had greatly increased. The limb was cold, the skin glazed and of a dusky color, the surface tissue was inelastic, and the skin was moved with stiffness over the subjacent fascia. He complained of twitchings in the forearm as well as in the arm, though in the latter to a less degree; but his chief distress arose from the constant pain, sometimes burning or shooting, but liable to become suddenly much more severe, and at times to be almost unbearable. Various measures for his relief were resorted to, but without success, and an operation was decided upon. The median nerve was cut down upon, and found to be thickened in itself and in its surroundings. After dissecting it away from the tissues about it for the distance of about an inch, it was forcibly stretched by pulling it downwards for about three-quarters of an inch. The wound was then closed. Some pain occurred on the following day, but none afterwards. One month after the operation the wound had healed, the arm was warm and had regained its natural appearance, and the patient was in all respects well.—*The Lancet*, June 26, 1875.

ON OVERWORK.—Dr. Samuel Wilks, of London, has taken occasion to reply to some of the views expressed in regard to overwork among intellectual men. He infers that in many instances they are not suffering from overwork, but from just the opposite state of affairs, and that in many others the result is due to a selection of occupation not congenial or interesting to the patient. Of course the amount of work which each man or woman is capable of performing is dependent on their temperament and especial powers, and can only be gauged by their individual capacities. Many people whose minds are never idle live to a good old age; when one object of study or pursuit is accomplished or becomes irksome, then it is time to take up some other occupation, and so divert the mind into other channels. Dr. Wilks finds that most of the persons who come under his care for overwork are those who have no occupation or object of interest other than their bread-earning employment.—*The Lancet*, June 26, 1875.

THE SIGNIFICANCE OF THE TEMPERATURE OF THE UTERUS.—From various examinations Bärensprung came to the conclusion that the child in utero possesses a higher temperature than the mother. The deduction from this, that the pregnant womb must be warmer than the vagina, axilla, or rectum, was established as correct by Schroeder, who made the former above that of the axilla and above that of the vagina. Schroeder and Cohnstein both utilized this fact to determine the life or death of the fœtus and the existence of pregnancy. Dr. W. Schlesinger, however, insists that a preliminary question to be answered is, whether the non-pregnant uterus does or does not have a higher temperature than the vagina; whether, in fact, the difference is due to pregnancy. He therefore undertook a series of measurements, using a thermometer with a curve like a sound, and having a perforated metallic sheath around the bulb to guard against breakage. Observing all due precautions and taking the average of many observations, he finds that in non-pregnant women the temperature in the vagina is higher than in the axilla, in the cavity of the uterus than in the vagina, and consequently in the uterus than in the axilla, in the vagina than in the rectum, in the uterus than in the rectum, in the cervical canal than in the axilla, and in the cervix than in the vagina. The higher temperature of the pregnant uterus over the vagina cannot, therefore, be ascribed to the pregnant condition alone, though the author agrees that the greater functional activity at that time would naturally favor it. Dr. Hölme, too, in his notice of Dr. Schlesinger's article, calls attention to the statements of Claude Bernard and others, that the temperature of the large parenchymatous organs is higher than that of the blood supplied to them, which is ascribed to their functional activity. Dr. S. would also expect to find the temperature of the pregnant uterus during labor higher than before that process set in.—*Wien. med. Jahrb.*, p. 427, 1874.—*Schmidt's Jahrb.*, 166, ii.

ON THE DISEASES ASCRIBED TO DENTITION, AND THEIR PATHOLOGICAL ADMISSIBILITY.—Dr. L. M. Politzer is inclined to differ very decidedly from the views held by A. Vogel regarding dentition and the diseases connected with it. He maintains that in the great majority of cases there is no such thing as catarrhal stomatitis accompanying the eruption of each tooth, the process going on so gradually and easily as not to be a source of inflammatory irritation, while the ulcers on the tongue, constituting stomatitis nec-

rosa, are due to friction on the tooth, which has already penetrated the gum. Nor does he think worthy of greater consideration the idea that the increase of the fluids of the mouth during dentition averts the danger of brain symptoms. He is much more inclined to attribute diarrhoea at this period to the ingestion of unsuitable food than to the irritation of dentition. He cannot recognize the periodicity and association with the eruption of the teeth, which Vogel maintains regarding various skin diseases. The various diseases occurring during dentition may all be observed at other times, and we should not attribute them to this cause unless all other known causes are absent. As to the great reflex irritability said to exist in childhood, and to be increased during dentition, he argues that it is astonishing to observe how well a young child will bear severe operations, very painful pathological conditions, and other powerful influences, without the development of reflex irritability; and why should we attribute to the comparatively easy and unimportant process of dentition an increased irritability which is not claimed for important physical, histological, and chemical changes going on in various important organs?—*Wien. med. Woch.*, xxiv., 49-51, 1874.—*Schmidt's Jahrb.*, 166, ii.

THE ACTION OF CERTAIN DRUGS ON THE SECRETION OF BILE.—Professor Rutherford, in an address before the members of the British Medical Association, in August last, detailed some experiments he had performed on dogs in reference to biliary secretion. These results were as follows: Croton-oil was not found to be an important hepatic stimulant; podophyllin stimulated the liver enormously, and caused the production of a bile almost the same as that which was secreted without its action; aloes was a very distinct hepatic stimulant, and produced far less intestinal irritation than podophyllin; rhubarb never failed to increase the secretion of bile, almost the same as that secreted without its help, while it caused less intestinal irritation than either podophyllin or aloes; scama stimulated the liver, but not to the same extent as rhubarb, and it seemed to render the bile more watery; colchicum caused the secretion of a large amount of biliary matter; taraxicum stimulated the liver, but not to any very great extent; scammony excited the liver, but not to a marked extent; calomel increased the secretion of bile in one experiment, but three others appeared to show that it was not a hepatic stimulant, at all events in the dog; gamboge produced strong intestinal irritation and profuse purgation, with a fall in the secretion of bile, probably owing thereto; castor-oil showed decided purgative action, but produced a slight stimulation of the liver; alcohol did not increase the secretion of bile. It thus appears that podophyllin, rhubarb, aloes, and colchicum had the most marked effect in increasing the biliary secretions of the dog; and as to their mode of operation, it appeared most probable that they were absorbed and directly affected the liver, though on this point it was not professed that anything had been definitely settled. These experiments were opposed to those of Dr. Bennett, in so far as that he found podophyllin diminished the amount of bile secreted. The apparent explanations of this difference, was thought to lie in the fact, that in Professor Rutherford's experiments the dogs were kept fasting seventeen or eighteen hours, while in Dr. Bennett's the dogs had their usual food. As regards calomel, the results were certainly opposed to clinical experience with man, though it was shown that in the dog, as in man, calomel produced purgations, and could also salivate.—*The Lancet*, August 14, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

GEORGE F. SHRADY, A.M., M.D., Editor

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, September 11, 1875.

ARMY HYGIENE AND CIRCULAR NO. 8.

THE medical profession is always ready to welcome a circular from the Surgeon-General's office. In the time of active war we remember that some of these were very terse and quite disturbed our official equanimity. But with the return of peace, under the intelligent supervision of the Surgeon-General, this branch of the war department set itself to work not only to collect all the valuable information as to health and disease which the war had furnished, but to place the army in all regards upon the best health footing. It has already made available to our army surgeons a medical and surgical history which shows the most careful tabulation and analysis. It is a contribution to the medical literature of the country, and an honor to the medical corps. Circular No. 8 is a report somewhat different from those which have preceded it, but having high claims to the careful study of all army officers as well as of surgeons and physicians. It is a recognition that a knowledge of hygiene is a very important prerequisite to efficient medical service in the army. The varied locations of posts, and the manifold changes which are necessary, together with unfavorable conditions which have to be abated where they cannot be wholly avoided, naturally introduce to the army medical officer the whole subject of sanitation. It is not remarkable that our ablest and most effective work on practical hygiene should be from the pen and experience of the Professor of Military Hygiene in the British Army Medical School. Our American army surgeons are on the alert in the same direction. We hope that the time is not far distant when every private soldier will have his pocket-book of sanitary information similar to that which Sir Garnet Wolseley prepared for the British service, or to Gordon's Soldier's Manual of Sanitation. No class of men have larger opportunities for careful investigation on all matters of locality and of health than our army medical men. Many of them had had

large experience in the field as well as in the camp, and now in a less active period have the finest opportunity for study and investigation. It is well that these studies should, as in the inquiries which gave rise to this Circular, be largely directed to sanitary matters. The great losses of armies, whether in camp or in field, are not accidents, but such infectious diseases as are fostered by bad regulations.

Liebermeister, speaking of the late Prussian war, says: "The singular exemption from disease was due in a great measure to the advances which the science of hygiene has made during our time." No better devotion to his army service can be rendered by the surgeon at the present time than an exact study of this department. On it the effective force both of a regular and volunteer army must ever depend. The Surgeon-General did wisely in assigning Assistant-Surgeon Billings to this duty. His large experience and his known assiduity and enthusiasm in this department has led him to devote much time to it. He has evidently spared no efforts to secure material for a valuable report. General Order 125 of the War Department made it the duty of all surgeons at posts to make full sanitary reports. Some of these are in a merely perfunctory way, but most of them show an intelligent appreciation of the importance of their observations.

Dr. Billings comments on the subjects related to the health of soldiers in the following order:

- I. Habitations, including barracks, quarters and guard-houses with their appendages.
- II. The food of the army and its preparation.
- III. The clothing of the army.
- IV. Hospital and medical supply.

It is readily appreciated that these are all matters fundamental to the condition of the army.

Defective ventilation is recognized as an evil in most barracks and quarters, but the barrack plans of 1873 are some improvement. Cleanliness and neatness of apartments is among the most valuable and difficult lessons to teach the soldier, and it must commence in strict regulations as to all quarters. This can only be attained when the government itself provides the necessary accommodation.

The special report of Surgeon Swart shows care as to the examination of the air of quarters. He throws doubt upon the correctness of the test generally used for organic matter, and gets results different from those of Hubbard and Parkes. In this and other reports the connection between imperfect ventilation and increase of diseases of the respiratory organs is everywhere recognized. The importance of bath-tubs as a supply to each post is rightly insisted upon. The fine uniform too often covers filthy linen and a soiled body. Habits of personal cleanliness must be enforced. The single bunk system is an improvement, as also the care as to proper bed furniture. In a hygienic point of view too little attention is given at home as well as in army life to this part of our clothing. Wire mat-

tresses and hair pillows, and clean linen and woollen coverings are largely influential upon comfort and health. Bad-clothes are the clothes we dress in about one-third of our time, not even counting the greater permanency of sickness. The Reports contain very many plans of hospitals, with descriptions. A comparison of these, and their study in relation to convenience and sanitary availability, is very important for every army officer. It is quite evident that the evils of hospitalism are not confined to civic life or fully relieved by tent methods. The effect of dampness on rheumatic and pulmonary diseases is well illustrated in the report as to Fort Monroe. We find but little new as to the arrangement of cess-pits. Those at West Point show how much depends upon porosity of soil. Where liquids are readily absorbed the drier fecal matter, protected from hot suns, is often left for a long time without injury to health.

The plan referred to in Columbia, South Carolina, is feasible in many cases. "Each company has a sink at a proper site. The sinks are deep trenches covered with a movable building. They are disinfected with lime and fresh earth. When necessary the buildings are removed and placed over new trenches, and the old trenches filled to their surface with earth."

A review of the section on Food shows that the ideas of a proper army ration have improved with an increased knowledge of dietetics. The soldier is no longer confined to jerk beef and hard tack, flavored with a gill of whiskey, but has a due share of variety in his daily food. There is some complaint that the rations do not yet correspond with the theoretical tables which measure the amount of force in each fibre, but these are not yet so perfect as to be absolute standards for comparison. As in the use of acids and various vegetables, we need to watch the results of a careful experience. The value of onions and of tomatoes, with their malic acid, has come to be well understood. The culture of the mushroom is recommended where feasible. The use of baking-powders is suggested for scouts and expeditions, but they should be made by known recipe, and not used as put up by most vendors. The soldier suffers more from bad cookery than from bad food. We are glad to see that attention is also directed to this. The water supply for cooking and drink is derived mostly from cisterns. In many parts of the country the ground-water is saturated with the products of vegetable decay, or in some wise unfit for use. Where the cisterns and the roofs are properly cared for, cistern water is undoubtedly to be preferred. The experience of the war suggested some valuable improvements in army dress. The new blouse and forage-cap are well approved, and the brass-screwed boots are more serviceable than those formerly provided. It is interesting to see the care with which the whole subject of clothing, in its adaptation to the soldier, is being studied by army medical men.

We have been much interested in comparing reports

from different posts and from different sections of the country. Such stations as that at Fort Steele and Fort Yuma show the effect of dry atmosphere. In the first, catarrhal diseases are spoken of as common. "It would seem that the very dryness of the air produces irritation by rapid evaporation from the mucous membrane of the air-passages. At least an unpleasant sensation of dryness and constant throat irritation is very perceptible to the new-comer. This irritation is enhanced by the deep expansive inspirations by which the organism apparently compensates the diminished amount of oxygen in the atmosphere. This dryness of the atmosphere, although in the beginning unpleasant and irritating, appears at the same time inimical to the development of serious pulmonary diseases.

The disease known as "Mountain-fever" is noticed as occurring at such places as Fort Bridger and Fort Steele, Wyoming Territory, and at several other localities. It is often referred to at outposts in the far West and in the Rocky Mountain region. Assistant-Surgeon Swart refers to it as a "remittent fever susceptible to the action of quinine, and well recognized as being indigenous, although the station seems free from intermittents. It has been called a 'modified typhoid'—typhoid without the enteric symptoms. The cases I have seen rarely reached this typhoid condition. . . . Most of the cases occurring in the garrison are seen at the first manifestations of disease, and are returned to duty in three or four days after treatment by mercurial purges, and twenty or thirty grains of quinine daily. If, however, the disease be permitted to run unchecked for a few days, the patient falls into a condition undistinguishable from typhoid, which often proves fatal among miners, settlers, prospecting and surveying parties."

Assistant-Surgeon Greenwell also calls it a remittent fever. "The most prominent symptoms are headache, severe aching through the whole body, insomnia, furred tongue, frequent full pulse, and constipation. Chills are infrequent. The efficiency of large doses of quinine proves the malarial origin. The mountaineers treat it with their panacea—sage tea—quite successfully. It is said that persons afflicted with ague rapidly recover in the same climate, as was illustrated by troops transferred from the Florida swamps. It is noted that erysipelas is more frequent than at frontier posts at lower altitudes, and is apt to complicate the most trivial injuries. The same fact was noted in a paper read last year before the American Health Association by a Pacific army surgeon. As erysipelas is usually regarded as zymotic, its history in this regard should be carefully studied. The favorable effect of the climate at Camp Douglas, Utah Territory, on asthma, is well illustrated by Surgeon Vollum. It is the boast of the people, as well as the physicians, that asthma cannot exist there excepting under a relieved and modified condition. Mormons, then, are not likely to die for want of breath. We should like to know more about the prevalent view that the bite

of a skunk is sure to be followed by hydrophobia (p. 279). It is quite important to find whether such an animal poison has all the specific character of typhoid fever, cholera, etc., so as to have but one origin, or whether it comes from some condition of system. An illustration of what small-pox can yet accomplish when unrestrained by vaccination, is afforded in the description of Fort Shaw, Montana Territory. "The Blackfoot Nation of Indians, from Dec. 2, 1869, to May 1, 1870, lost 1,400, out of a population of 7,000 or 8,900, by this disease." They would have lost many more, but a part of the nation had already suffered from the disease. We commend the fact to the Indian Commissioners.

Outside of the strictly hygienic sphere there are many descriptions of localities which give us some idea of the wonders and exposures of frontier life.

We commend the entire report to the close study of all army officers, and the civil physician and surgeon will find in it much that is interesting and profitable. Such reports do much to elevate the standard of health both in military and civil life. If our legislators could only appreciate how much the welfare and defence of the nation depend upon well-sustained validity, instead of nursed and chronic invalidity, such as is often created by defective sanitation, they would not be slow to improve all army arrangements bearing on the health of the soldier.

THE MARINE HOSPITAL SERVICE OF THE UNITED STATES.

THIS department of governmental relief to the sick sailor is gradually assuming important proportions. From the small monthly sums deducted from the wages of the crews of vessels of all kinds, a fund is formed which is expended under the administration of the Marine Hospital Service, a subdivision of the Treasury Department, in their care and treatment when sick and disabled. This relief, we learn from the Annual Report just issued, includes medical and surgical treatment, medicines and appliances, food, shelter, hospital clothing, washing, nursing, etc., and the expenditures cover the cost of the foregoing, together with that of isolated treatment of contagious diseases, the transportation of patients to hospital ports, the burial of the dead, etc., and all other disbursements on account of the service, except for repairs, etc., to hospital buildings. During the fiscal year 1874, 400,452 days of relief were furnished, at 91 ports, at a cost of \$400,951.58, to 14,364 seamen, 12,605 of whom were treated in hospital for an average period of 31.6 days each, with a mortality of about 3½ per cent. Hospital dues were collected to the amount of \$346,676.31 at 130 ports, leaving \$54,275.57 to be made up in the deficiency appropriation by the government. The average annual cost of each patient was \$27.91, but only \$24.14 of this amount was defrayed by collections of hospital money, the

net cost to the government for each patient being thus \$3.77. By the judicious administration of the service in the hands of Dr. J. M. Woodworth, Super-vising Surgeon, the usefulness of this mode of relief has been much enhanced, and system imparted to a branch which, but a few years since, was conducted with anything but order and regularity, and with much greater expense to the department.

Reviews and Notices of Books.

CYCLOPEDIA OF THE PRACTICE OF MEDICINE. Vol. III. Chronic Infectious Diseases. By PROFESSOR CHRISTIAN BAEUMLER, PROFESSOR ARNOLD HELLER, and PROFESSOR OTTO BOLLINGER. American Edition. New York: William Wood & Co., 27 Great Jones Street.

NEARLY one-half of this volume is given up to syphilis, and the subject is treated in a thorough and even manner, while the style is excellent, making the article a very readable one. As regards the long debated question of the time at which the disease originated, the author thinks there is good reason to believe that it was neither carried over to Europe from the West Indies by Columbus's men, nor did it originate with the army of Charles VIII., where it committed such frightful ravages in 1494-5, the probabilities being that it was known in very early times, though apt to be classed with other diseases, such as leprosy. The violence of syphilis may be said to have abated very considerably since the fifteenth century, though in some localities it occasionally assumes a particularly intense character. The reader will naturally be interested in the author's views, as to what lesions of the disease may produce infection. It seems to be inferred that all secondary lesions have this power, though it is doubtful whether the substance of gummy tumors and ulcerating tubercles—the lesions of tertiary syphilis—have any such quality. In the majority of cases where secondary lesions produce the disease it is communicated by the act of *kissing*. This statement may explain one of the ways in which innocent persons take the disease, and should lead to an appreciation of an important point—the danger which may follow from indiscriminate kissing, especially of children by nurses and friends. More than this, married women not infrequently take the disease, and thus may be the unconscious agents which spread it.

As to the question of the transmission of syphilis by vaccination, the author holds the opinion that it is so transmissible.

If syphilitic children be vaccinated, the pustules may appear to be perfectly normal, and yet if the pustular matter be employed for further vaccination, syphilis may follow.

And yet, on the other hand, it may not follow, or both syphilis and vaccinia may occur together. These facts, the author states, he has derived from the records of quite recent cases, and they will give some color to the objections that always are urged against the use of humanized virus, when the question of compulsory vaccination is brought up.

As to the unity or duality of the chancre poison he inclines to an opinion that is somewhat at variance with those commonly held. He believes that syphilitic

infection does not possess the pure and simple character observed in pathological experiments. There is, he says, but one syphilitic poison, but not in the sense given to it in the doctrine of unity. He does not regard the contagious principle of chancre as identical with this poison. It is a pathological agent by itself, but a far less constant and uniform one than the poison of syphilis, and may be generated *de novo*, under certain circumstances, quite independently of syphilis.

The whole subject is treated in a clear manner, and it may be regarded as an excellent exposition of the subject. Copious references are made to all the best known syphilographers, those of our own country not being neglected.

Somewhat over 200 pages are devoted by Bollinger to infection by animal poisons, especial attention being paid to glanders, malignant pustule, hydrophobia, and the foot-and-mouth disease. Though the author is but little over thirty years of age, as we see by the biographical notice at the commencement of the volume, he has already contributed largely to medical literature. Having acquired a general medical education, he then devoted himself to veterinary medicine, of which he is now a professor in Munich. He has therefore had the requisite experience to make him a proper authority on those diseases which are common to man and animals. The author, in a note to the American edition, proposes the use of new terms, which he afterwards adopts, as substitutes for "contagium" and "miasma," terms used by Liebermeister and others, the former to indicate a poison generated *within* the body, the latter a poison generated *without* the body. Bollinger proposes to call the one *endogenous*, and the other *exogenous*.

It seems a pity, however, now that we are getting into the way of using and understanding the terms "contagium" and "miasma," in the sense just given, that we should be made to change them for others, both of which have already two distinct meanings, one in histology, as indicating the way in which cells multiply, and the other in botany.

One of the most noteworthy facts which Bollinger brings forward is the communicability of the foot-and-mouth disease from animals to man. This is usually effected either by the consumption of unboiled milk, or by direct contact of the hand during milking with the vesicles on the udder, or by contact with the saliva of infected animals.

The disease fortunately is benign, but precautions should be taken when such animals are known to have the disease, and their milk should never be consumed unless boiled.

In malignant pustule, we are told, contrary to the authority of Bouley, that the specific poison is due to parasitism, which Davaine first observed, and called bacteridia. These organisms are believed by the author to be the actual poisonous principles, and not merely the carriers of it, as some hold. The disease is sometimes contracted in killing or dressing animals, or by eating the diseased flesh, or insects, as the blue-bottle fly, may carry and insert the poison, or it may be inoculated from man to man, or finally the poison may enter the body with the air and food. The best treatment is deep crucial incisions into the part, followed by cauterization. Generally a single thorough cauterization will effect a cure.

The remainder of the book, about 100 pages, is occupied by the "Diseases of Migratory Parasites," and is very largely illustrated by wood-cuts, many of which are by the author.

The chapter devoted to Trichinae will naturally attract a great deal of attention, as it contains a large

amount of new and interesting material. As the treatment of the disease has as yet been entirely unsatisfactory, the author has given a great deal of attention to the prophylaxis, and laid down careful rules for the inspection of pork. He claims that American meat is peculiarly liable to the disease, especially the salted bacon. Of 622 sides examined at Rostock, twelve were found trichinous, or one in fifty-two. In Elbing one in twenty contained them. Salting and smoking, unless done very thoroughly, afford no protection against infection. Microscopic inspection of the meat should be insisted on, as has been practised in Brunswick since 1863, with excellent results.

General instructions should also be given as to how these meats are to be cooked, and hogs should be protected by proper legislative enactments against trichinae, so as to stop the sources from which they may come. This volume will be closed with the impression that it is a peculiarly interesting one. The large amount of new material that it contains makes it a valuable contribution to the literature of the day.

FIBRO-PLASTIC INFILTRATION INTO THE LIVER OF THE FŒTUS AND NEW-BORN, CAUSED BY SYPHILIS. DE QUELQUES MANIFESTATIONS DE LA SYPHILIS CONGÉNITALE, ET CŒT. By T. DE ROCHERDRENE. Paris, 1874.

The author, under the supervision of Gubler, has studied very carefully certain lesions of hereditary syphilis, first described by the latter, and has given a very clear description of them, while at the same time he confirms and elaborates Gubler's views. The clinical portion of the author's work is very full, as he gives details of nineteen observations from which he drew his conclusions; as these are given by the author in an aphoristic form, we quote them as giving a fair analysis of his book.

He thinks that he has demonstrated:

1st. That the fibro-plastic infiltration into the liver, one of the most serious of syphilitic lesions, and discovered by Gubler, is much more frequent than was supposed.

2d. That commencing in the early months of intra-uterine life it shows itself shortly after birth.

3d. That it is invariably accompanied by other manifestations peculiar to syphilis, and that it rarely fails to coexist with changes in the thymus and lungs, in which R. states that he thinks that he has discovered a lesion not yet known.

4th. That the most marked symptoms of the lesion of the liver consist in a peculiar dark wine-red discoloration of the lower extremities, and in dropsy.

5th. That the dropsy is caused by hepatic obstruction, and that it is not, as claimed by Desruelles, a secretion of the peritoneum.

6th. That the peritonitis is not secondary to the infiltration, as it is but rarely met with.

7th. That another important point is the character of the urine, which contains hemato-globuline and albumen.

8th. That in the two forms described by Gubler, there exist varieties little known, which confirm his opinion, tending to assimilate the infiltration to the gummata and to syphilitic sarcocele.

9th. That in the coexistence of secondary and tertiary lesions of newly-born syphilitic children, there is reason for thinking that there is a period of transition.

10th. That inoculation of the liquid from a syphilitic infiltrated liver produces that disease.

11th. That the influence of the father is most potent in producing these lesions, as he is the sole cause of the infiltration.

12th. That the hepatic infiltration is exceptionally grave.

13th. That a rational treatment should be administered with promptitude and energy.

14th. That taking into consideration how they are borne by the patients, mercury and iodine in combination should be used.

15th. That mercurial friction and sublimate baths are so efficacious that internal treatment will not be necessary.

16th. That mother or nurse, whether healthy or syphilitic, should be treated with the child.

It is well, perhaps, to point out certain errors in statement and conclusion in this quite good brochure. Rochelonne says that the father alone is the cause of this form of liver lesion—in other words, of the syphilis. Now this is entirely at variance with our knowledge, and with the results of clinical observation, since it is impossible that a child so saturated with syphilis could be born of a mother who did not become syphilitic. This is a return to the hallucinations of Von Barenprung which very much surprises us. As to the question of treatment there are inherent disadvantages to the use of sublimate baths upon infants, as well also are there drawbacks in the use of mercurial frictions, which, though *sometimes* useful in infants, cannot wholly replace a well-regulated internal mercurial course. The last conclusion strikes us with some surprise. It is sufficient to know that if a mother brings forth so thoroughly a tainted offspring as to have visceral lesions, the imperative duty of the physician is to treat her energetically, as she must of necessity be in an active stage of syphilis. As to the nurse, it certainly is not less than criminal to put such a child to a woman who has not had syphilis, for fear of her infection, and if she is syphilitic, the duty is obvious. As critics we must say that it is somewhat astonishing to find such careless reasoning on some subjects, while others are so intelligently handled.

MANUAL OF COMPARATIVE ANATOMY AND PHYSIOLOGY.

By S. MESSENGER BRADLEY, F.R.C.S., Senior Assistant Surgeon Manchester Royal Infirmary. Third edition. Published by Lindsay & Blakiston, Philadelphia, 1875.

A HANDY book, and one which the constantly increasing class of natural history students will find well worth owning. The second chapter, devoted to the "Theory of Evolution—Sketch of Evolution of the Animal Kingdom—Phylum of the Sub-kingdoms," seems rather too conspicuous, considering, as the author tells us, "the evidence is imperfect." The arrangement of the subject-matter throughout the book is good; and the numerous definitions in the text may render very acceptable aid to many who are not proficient in the classics, but are, nevertheless, earnest workers in science. The author starts out with a thorough explanation of many of the more important terms now in use among naturalists, and adds a pretty full glossary at the end of the volume.

The descriptions and definitions are very concise and clear, and the matter very liberally illustrated by wood engravings. Of the wood-cuts we cannot speak in the highest terms, regarding them as works of art; yet they answer their purpose perhaps fully as well as more highly finished work.

As a manual of the subjects of which it treats this book will certainly be acceptable to students, and particularly to the many professional men who find time only that is snatched from other duties, and who, from such a convenient exhibit as is here made, may contrive to take in much valuable information

which is lost in efforts to glean from more ponderous volumes.

To those who are interested in the theories of "Evolution," the three plates given on pages 8, 9, and 10 will prove acceptable; the first "showing in Outline the probable Channels through which the various Sub-kingdoms have passed during their Evolution;" the second, "Phylum of the Sub-kingdom of Vertebrata, showing the probable genealogical arrangement of the classes and principal orders;" the third, "Phylum of the Animal Kingdom, showing the probable genealogical arrangement of the principal classes." The book has the merit of being an exposition of the latest and most approved arrangement of the animal kingdom, and at the same time one remarkably attractive throughout in its adaptation to the student's uses. There is a system in the arrangement of the subjects which is admirable, particularly as compared with the contents of many books of this character.

LESSONS IN ELEMENTARY ANATOMY. By ST. GEORGE MIVART, F.R.S., etc., Lecturer on Comparative Anatomy at St. Mary's Hospital, author of the "Genesis of Species." Macmillan & Co., London, 1873.

THIS little book will be found to be in a great measure what it claims, a *vide mœrum* for the student in human morphology, and that type of structure to which man's body belongs. Great prominence is given in the work to the skeleton, for which the author gives several good reasons, and adds: "Moreover, it is a recognized maxim with teachers of (exclusively) human anatomy that a thorough knowledge of the bones is not only a necessary preliminary to other anatomical knowledge, but that the latter is acquired with comparative ease when the first has been well mastered. I have deemed it advisable to act on this maxim in teaching the anatomy generally of man and of the animals herein referred to."

The book is divided into lessons, the first of which is devoted to a general view of the animal kingdom. The various types of structure are shown by small wood-cuts, and throughout the body of the work the illustrations are profuse and valuable. Through such books, which are of convenient size, easily handled in spare moments, the professional man, as well as others more nearly identified with such studies, may gather a goodly store of knowledge.

TRIPLET BIRTHS.—M. Depaul lately submitted to the Academy of Paris the placenta of a triplet born at Bordeaux. The three children were females, and were, when the case was reported, still alive and in good health. The placenta formed an entire mass; the three cords were perfectly distinct; one was inserted in the centre of the placenta, another on the edge of this organ, and the third on the membranes. There were three amniotic pouches, which were rather difficult to trace on the specimen; but, according to the report of the medical gentlemen who forwarded it, there were, during parturition, three distinct ruptures of the membranes, which took place before the birth of the children. By a remarkable coincidence, the Paris papers have reported that a *conciergerie* in Paris has given birth to triplets, two boys and a girl. The mother is aged thirty-five, and has been confined for the third time. The boys, who were in the same amniotic sac, were born first, at an interval of an hour between each; the girl, who was in a separate sac, was born half an hour after the last boy. The three are alive, well formed, and sufficiently strong—particularly the first boy and the girl.

Correspondence.

RECIPROCAL INTERESTS OF PHYSICIANS AND PHARMACISTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The sensible article by Mr. Sayre, in a recent number of your journal, should attract the attention of the profession to some of the practical points in which doctors and apothecaries are mutually concerned. His suggestion, that distinct directions for the use of the medicine be written on the prescription, is judicious and proper; as the adoption of that plan would prove a safeguard to all parties. For it cannot be denied, as shown by Mr. S., that physicians have occasionally made the most fearful errors in writing prescriptions, which might, but for the intelligence and vigilance of the apothecary, have cost the sacrifice of the patient's life and of the doctor's reputation. Yet I have known of the apothecary being treated in the most indignant manner, after having privately and courteously informed the physician of his error, and prudently requesting the messenger to call again when the medicine should be ready.

In one such instance the prescription was brought back to the apothecary and torn up in his presence, whilst the customer was forbidden ever to go to the store again. On the other hand, an eminent practitioner, whose medicine would have proved fatal had his prescription been filled, called upon the apothecary and thanked him in the most cordial manner for having discovered and cautiously communicated to him the error he had made.

How mistakes on our part are to be prevented is an important question. In reply, I know of no better method than that of a late prominent member of the profession, who *invariably* laid his prescription aside a few moments, and then read it over carefully and critically. The frequent accidental substitution (as I am informed) of the word morphia for quinia, and the omission of camph. when prescribing paregoric, should awaken every physician to the value of the above precaution, which, I confess, I have had occasion myself to appreciate in several instances.

It has happened in some of the finest drug stores in this city, that in a multitude of prescriptions there has been a transposition of them, resulting in narrow escapes from misusing the medicines. In one case one drachm argent. nitrat. intended for solution and vaginal injection, was actually swallowed as a powder by the wrong patient; and in another case a patient just escaped taking a dose of liniment which should have been sent elsewhere. Facts like these might be multiplied, and call loudly for some certain means of preventing their recurrence. The only sure plan is for the physician *always* to put the name and residence of the patient, and his own name, on the prescription, with explicit directions for the use of the medicine; and there certainly can be no objection, especially when more than one medicine is prescribed, to adding, where appropriate, a label of "Cough Mixture," "Fever Mixture," "Liniment," "for external use," etc., to increase the protection against accidents; for liniments containing croton oil, aconite, etc., have been swallowed from omission of this simple precaution. The treatment of one such case of accident will cost us more toil and anxiety than a lifetime of precautionary methods.

Apothecaries often justly complain of the *illegible*

writing and *severe* abbreviations of many physicians; the perplexity and danger in this view are too apparent not to command the serious consideration of even the most intelligent in our profession, and a reform in these respects is strongly hoped for.

In turn, some apothecaries may be censured for risk of errors on their part. The compounds of one kind of medicine are often placed in a row on the same shelf; for instance, Tart. Antimon.—Pulv. Antimon.—Hydrarg. Bichlor.—Hydrarg. Proto-Chlor.—Pulv. Ipecac.—Pulv. Ipecac. Comp.—Tinct. Opii—Tinct. Opii Camph., etc. In my own experience, a quarter of a century ago, I fortunately discovered that an apothecary had substituted tart. antimon. for pulv. antimon. in my prescription for a child. At another store, sixty grains of Dover's powder were put up instead of my prescription for one drachm of pulv. ipecac, as an emetic for an adult. The least pardonable of all was an instance in which an apothecary gave one ounce of arsenic for that quantity of pulverized gum arabic, intended for a demulcent solution. The patient, a married lady, had a narrow escape from death. Her husband was determined to prosecute the young man, but his tears and entreaties, with my intercession in his behalf, spared him that penalty.

What safeguard shall be thrown around all these dangers? It is only to keep *poisonous* medicines *apart* from simple ones, adopting as an *invariable* rule (practised by a leading pharmacist of this city), that in filling a prescription no bottle or drawer shall be replaced without a fresh inspection of the label on it. This is taking for granted that no medicine is ever kept except under its correct and proper label. The apothecary should be familiar with the doses of all medicines, to enable him to discover when a physician has probably directed a larger dose, or other medicine than he intended, and by informing him in a way that the messenger shall not know it.

Fortunately, by recent legislative enactment, medicines can be dispensed only by those who have passed a rigid and satisfactory examination in all the departments of pharmacy and chemistry, as a testimonial of their ability to fill their responsible positions; and physicians now have some protection in the apothecary's perfect qualification for the duty he undertakes. Nevertheless, it is advisable for him to select those of reputation in the various localities he may visit in, to whom his prescriptions shall be sent with entire confidence, instead of allowing a messenger to go to the nearest store as a matter of convenience, regardless of the freshness and quality of the medicines to be used.

The important occurrences here cited are of so remote a date that I believe nearly, if not quite, all of the parties alluded to are either no longer in the business, or are not living, so that no one at present engaged in it need make a personal application of them; whilst the authenticity of the facts furnishes an experience and suggestions which physicians and pharmacists may advantageously avail themselves of in the future.

"MEDICUS."

THE EUCALYPTUS is becoming quite the fashionable tree in the South of Europe. There are fine specimens in the public promenades of Nice and Cannes, and in many of the towns of Spain. Garibaldi is urging that it should be planted around Rome in order to prevent malaria, and his desires are likely to be fulfilled. Its health-giving properties, which were in course of discussion only recently, now seem to be fully admitted.

HOSPITAL CONSTRUCTION IN THE ARMY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Since the date of the famous edict expunging calomel and tartarized antimony from the military materia medica, we have assumed Medean and Persian omniscience to be an *ex-officio* attribute of the Surgeon-General's bureau, and especially with regard to matters nosocomial have we supposed its decisions to be final; but the recently issued circular concerning the hygiene of the army suggests a distressing suspicion, either that the official mind may change, or that the official definition of words is subject to arbitrary and confusing reversal. In 1870 our previous convictions were confirmed by the authoritative announcement, in circular No. 4, that "the true principle of hospital construction" was that of isolated pavilions, which method, "known as the pavilion plan, . . . is now recognized as the best suited to its purpose, the experience gained during the late war having contributed greatly to the recognition of its value in this country." But now, in 1875, the same writer tells us that "the 'pavilion plan,' which for a time was supposed to be a perfect panacea against all evil, has been found by sad experience to furnish no security against the evils summed up in the word hospitalism, and the results of practical trial in recent wars, both in this country and in Europe, have led to the recommendation of the so-called barrack-hospitals, that is, temporary wooden structures intended to last but ten or twelve years," in which "no ward or room for patients should have another room over it."

The apparent contradiction may perhaps be due to the writer's forgetfulness of the sense in which he used the term pavilion five years ago, or to his belief that that which we call a pavilion if called by any other name will smell sweeter; but that the meaning attached to this term during the interim has closely corresponded with the present signification of "barrack," may be judged from the reports of the Supervising Surgeon of the Marine Hospital Service, who in 1872 particularly advised building "all the hospitals of wood, and destroying them after ten or fifteen years," and who again, in 1873, urged that hospitals "should consist of pavilions, or separate detached buildings of wood, one story in height preferable, . . . constructed with the view of destroying them as soon as the peculiar hospital diseases—erysipelas, pyæmia, gangrene, etc.—are engendered by the cumulated miasm of the patients, a condition usually obtains after the continued use of a ward for ten or fifteen years, the time depending mainly upon the amount of air-space to each patient, and the character of the ventilation." C*****

ANOTHER CASE OF REMARKABLE RECOVERY FROM GUNSHOT WOUND.

PASSAGE OF BALL PER RECTUM ON THE FIFTH DAY.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—The case of "Pistol-shot Wound of the Abdomen," reported by Dr. Wm. O'Meagher in THE MEDICAL RECORD of July 17th, and the report of a case of "Gun-shot Wound of the Abdomen," by Dr. Josiah F. Day, in THE MEDICAL RECORD of August 14th, recall another very unique instance of injury to the chest and abdomen, terminating in recovery, which came to my notice during the late war. Notes of the case, taken by Dr. Jomain of the 29th New York Volunteers and myself, were sent to the Surgeon-General, and

referred to in "Circular No. 6;" but that document had a very limited distribution, and so seldom have cases of the kind been recorded that it may be of interest to allude to it again. Captain Robert Smith, of the 29th New York Volunteers, was wounded at Chancellorsville, Va., on the 2d of May, 1863. The missile was a round musket-ball weighing about four hundred grains; it entered the eighth intercostal space of the left side at a point nine and a half inches to the left of the ensiform cartilage, fracturing the ninth rib, and without wounding the lung passed through the diaphragm and entered some portion of the alimentary canal. Captain Smith walked over a mile and a half to the rear, and on the 3d day of May presented himself at the field hospital for treatment, apparently not in the least fatigued by his journey. On examining the wound a hernial tumor of the lung was found protruding, of the size of a small orange.

A ligature placed around it on the field by surgeons who tried ineffectually to reduce the hernia was removed, and the splacelated portion easily separated from the healthy granulating surface beneath.

The bowels having remained in a constipated condition after the injury, an ounce of oil was ordered on the 7th day of May, five days after receiving the wound, and while at stool, a few hours after, the ball was voided. It was somewhat battered from striking the rib, and quite irregular enough in shape to have made more serious trouble than resulted along its dangerous track. The patient daily walked about the ward smoking and chatting with his comrades, apparently enjoying the most comfortable physical condition. He never suffered from cough or dyspnoea, never had had anything like shock or constitutional disturbance whatever, and no sign or symptom of peritoneal inflammation from first to last. Cold-water dressings alone were applied to the hernia, and with no other special treatment it gradually diminished in volume until the 2d of June, when it was so much reduced in size that Captain Smith was transferred to Washington and given a furlough of sixty days. After his return he was again examined, and the wound found to be entirely healed, the respiratory sounds were normal, and there was still a slight hernia of the lung.

Mr. Stauch, artist of the Army Medical Museum, made a drawing of the parts.

In this case it is certainly very remarkable, taking into consideration the size and weight of the ball, that there should have been so little constitutional irritation, and such an entire absence of the symptoms of that inflammatory process which is absolutely necessary to recovery. In reference to the abdominal lesion, it seems to me probable that the small intestines escaped injury, and that the ball passed into the transverse or descending colon, which is much less likely to take on inflammatory action than the smaller bowel, thus happily avoiding that dire and intractable affection of the serous membrane. In this instance the ball undoubtedly passed immediately into the intestine, as it also must have done in the case reported by Dr. Day, for the slower process of ulceration would certainly result in very considerable inflammatory action, the symptoms of which would not escape observation. Why the contents of the bowel did not escape into the peritoneal cavity, and how so large a missile could find its way into the intestine without giving rise to the most violent inflammation, are questions about which we may conjecture or speculate, but cannot satisfactorily answer.

WM. H. HOAG, M.D.,

Late Surgeon 134th New York Volunteers.

MANHASSET, L. I.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from August 29th, 1875, to September 4th, 1875.

WEBSTER, WARREN, Surgeon.—Granted leave of absence for one month. S. O. 174, A. G. O., August 30, 1875.

MIDDLETON, J. V. D., Assistant Surgeon.—Leave of absence further extended one month. S. O. 49, Headquarters of the Army, August 30, 1875.

AINSWORTH, F. C., Assistant Surgeon.—Assigned to duty at Fort Vancouver, W. T. S. O. 115, Dep't of the Columbia, August 19, 1875.

NAVY.

Aug. 31.

DAVIS, WILLIAM B., Passed Assistant Surgeon.—Ordered to the Receiving Ship *Sabine*, at Portsmouth, N. H.

BLACK, C. E., Assistant Surgeon.—Ordered to the New York Navy Yard.

HUDSON, ADRIAN, Surgeon.—Ordered to the Washington Navy Yard.

HILLAND, THOMAS.—Detached from the Washington Navy Yard, and ordered to duty as a member and recorder of the Naval Examining Board at Washington, D. C., on the 15th inst.

Medical Items and News.

PORTABLE BATHING APPARATUS.—PROF. A. B. CROSBY exhibited to the New York Medical Journal Association a portable bathing apparatus which facilitates the use of water in the treatment of fevers and other diseases.

It consisted of an india rubber sack of exceptional strength, of nearly the shape of an ordinary bath-tub, and fastened to a wooden rim, which had been made of the shape of a bathing tub by first steaming and then bending it. A wooden collar was attached to the rim at each extremity of the tub, which supports it when placed upon a couple of chairs for use. It is then secured to the chairs by means of cords, or if desired one end may be fastened to the top of the chair while the other rests upon the floor, and the sack can be made shallow by means of cords passing beneath it and then fastened to the rim. With this apparatus a full or half, or sitz or foot-bath can be given with the greatest ease, and can be done in the room of the patient, thereby avoiding any disturbance which might attend moving him from one room to another.

Dr. Crosby referred at some length to the labors of Dr. Nathan Smith and his own father, both of New England, in the treatment of the typhus of their day. Water entered largely into their method of treatment, and their success was a matter of common notoriety over that entire section of their country.

With regard to cold water for bathing purposes in the treatment of fevers, it is known to all that cold produces a shock, and in proportion to the shock given will be the height of the reaction. Therefore in order to obtain a continued benefit it will be necessary to repeat the application of the cold, perhaps very often, to keep down the reaction.

In all ordinary cases he is inclined to believe that as much benefit can be derived by using the spring-bath,

with water at a temperature of 85° or 90°, as from the use of cold water. There is no shock produced by the warm water, and when its application is accompanied by a certain amount of friction and the surface is left somewhat moist, the heat of the body is diminished in the most agreeable manner possible. When the surface is left a trifle moist the heat of the body produces a rapid evaporation, and with this comes the production of cold. As a rule, therefore, in all advancing cases of elevation of the temperature of the body, he directs that his patients shall be sponged with warm water, always leaving the surface moist. As an illustration of this method of using water and the benefits which attend it, he cited the treatment of 120 cases of measles while in the army. His rule was to have the man sponged with warm water, night and morning, and not infrequently at noon while scaling, and not only, by unanimous consent, added very much to their comfort, but not a single case proved fatal.

BRITISH MEDICAL ASSOCIATION.—The next meeting of the British Medical Association will be held at Brighton, under the presidency of Sir John Cordy Burrows.

THE CHICAGO MEDICAL JOURNAL AND EXAMINER is under the editorial management of Dr. William R. Byford, who has as his associates Drs. James H. Etheridge, Norman Bridge, James Nevins Hyde, and Ferd. C. Hotz. The journal, as now conducted, belongs to a stock corporation known as The Chicago Medical Press Association.

INSPECTOR-GENERAL H. FRANKLIN, C.B., who died at Folkestone, England, on the 2d of August, aged eighty-two years, was a surgeon in the British army at the battle of Plattsburg.

THE DECORATION OF THE LEGION OF HONOR has been conferred upon Dr. Bormennais, Physician-in-Chief of the Hôtel-Dieu of Toulouse; Helson Batut, Surgeon-in-Chief of the Hospitals of Toulouse, and Dr. Th. Desclaux, the Mayor of Tonniens, for their actions during the recent inundation.

BOSTON MEDICAL LIBRARY.—The physicians of Boston held a meeting on the 20th of August for the purpose of organizing a medical library, to consist of medical and scientific books, journals, and pamphlets, for ready reference. Offers have been made of pamphlets and journals, and of one or two private libraries. More than one hundred members have already joined, and the rooms are to be opened in October.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

[THE MEDICAL RECORD is published every Saturday. Notices of meetings, lectures, operations, etc., intended for publication in this bulletin should be received at the office, 27 Great Jones Street, one week previous, to insure their appearance.]

Tuesday, Sept. 14th.—East River Med. Assoc.

Thursday, Sept. 16th.—N. Y. Acad. of Med., 12 W. 31st street.

Monday, Sept. 20th.—Sect. of Obstetrics, N. Y. Acad. of Med.—N. Y. Soc. of Neurology and Electrology.

Tuesday, Sept. 21st.—N. Y. Obstetrical Soc.—Med. Soc. of the Co. of Kings.

Wednesday, Sept. 22d.—N. Y. Pathological Soc.

Thursday, Sept. 23d.—N. Y. Medico-Legal Soc.

Original Communications.

CONSUMPTION: ITS HISTORY, PATHOLOGY, AND TREATMENT.

By EDWARD C. MANN, M.D.,

MEDICAL SUPERINTENDENT STATE EMIGRANT INSANE ASYLUM,
WARD'S ISLAND, NEW YORK.

As we propose to treat of a branch of medical science which has always attracted the attention of physicians, from the difficulty experienced in determining its precise origin and nature, and which has given rise to widely diverse opinions, it may, perhaps, be interesting, and will certainly be necessary for a clear comprehension of it, to trace back both this disease, and the various opinions respecting it, to the earliest period from which we are enabled to learn anything of its history.

We find the first mention of consumption made in the works of Hippocrates, and when we reflect upon how little was known of medicine in the early ages, it is surprising to find to what correct general ideas Hippocrates arrived in his researches upon consumption.

Hippocrates classified consumption into five varieties: First, the disease that is now known as chronic pneumonia, which is an inflammation involving the walls of the air-vesicles, and the interlobular connective tissue; the second he considered to be owing to the dropping of mucus from the head down into the lungs. It is probable that he refers here to chronic catarrh. The third was caused by venous bleeding, by which term he probably referred to hemorrhage proceeding from a branch of the pulmonary artery, which conveys the venous blood from the heart to the lungs for purification. Fourth, by a collection of blood, pus, and mucus in the pleural cavity; while the fifth were abscesses or ulcerations in the lungs, by which he probably intended to designate what we now denominate tuberculosis of the lungs. These conclusions, at which Hippocrates arrived relative to consumption, governed the world for two thousand years, until the year of our Lord 1614, when Franciscus Deleboe Sylvius made important additions to this branch of medical science. He called the hard collections of matter found in the lungs of consumptive tubercles, and was the first to recognize the process of softening of the tubercle, thus forming cavities in the lungs and destroying them. He also wrote of a consumption of the blood. The views advanced by Hippocrates and Galen, and revised and corrected by Sylvius, underwent no particular advancement until the year 1689, when Morton, of London, published a work upon consumption that attracted great attention. He took a stand much in advance of anything before known upon the subject, and his views were acknowledged for more than a hundred years. He defined consumption as "a wasting away of the body," attended by fever, and dependent upon a diseased condition of the lungs which culminated in ulceration of them. His pathology was, that the acid and diseased serum of the blood exuded into the lung tissue, and acting as a foreign substance, irritated it and caused inflammation and ulceration. He recognized but one kind of consumption, and that was caused by the presence of tubercles. He also believed in an hereditary consumption, and an accidental or acquired one. About the year 1800, Auenbrugger made the discovery of determining the progress of consumption by percussion, a process by which we are enabled, by

the relative high or low notes elicited by thumping upon the chest with the fingers, to determine with comparative accuracy the amount of disease which exists. The next discovery of note was made by Bayle, who described what is now called miliary tuberculosis. Bayle was followed by Laennec, whose name has become immortalized by his discovery of auscultation, a method by which, through the sense of hearing, we can determine the progress of certain diseases of the chest that can be ascertained in no other way. Laennec believed in but one kind of consumption, "tubercular consumption," and described with great accuracy the gray and yellow tubercle. This theory of "tubercular consumption," which was based upon the erroneous idea that consumption is always caused by the presence of tubercles, was combated successfully by Andral, who proved beyond doubt the existence of an acute phthisis or inflammatory consumption—"galloping consumption"—which resulted from degeneration of coagulated blood, retained in the air-vesicles from bronchial hemorrhage. In the year 1850 Reinhardt also succeeded in proving that Laennec was wrong, and went back to the old idea of Hippocrates, that tubercles were nothing but the result of inflammation, and established the theory that consumption in its different forms was but a chronic pneumonia with different physical signs. Although anatomy had disproved the old ideas and theories, nothing positive could be found to rely on as a foundation, until Virchow appeared, and by his "Cellular Pathology" laid the corner-stone of medicine as an exact science, and demonstrated the pathology of consumption beyond the line of dispute. The late Prof. Felix von Niemeyer adopted and made practical use of Virchow's discovery, and did more than any of his contemporaries to place upon a firm foundation the pathology of consumption. His researches, relative to chronic pneumonia, which according to our best writers comprises more than one-half of consumptive cases, has been of inestimable value to science, and we can only regret that this most eminent German pathologist and physician was not spared to us for a longer time.

Pathology of Consumption.—All organic life is composed of one or more cells, the lowest form of life being a single cell, while the highest form of life, or the human body, is composed of an infinite number. The lowest forms of cells are propagated by spores, which originate in the mother cell, and finally penetrate the cell wall and live an independent life; while the highest forms of cells are propagated by a budding out of the cell wall and gradual detachment of this newly formed cell. These highest forms of cells, which are those composing the human body, do not live an independent life as the lower ones do, but are dependent upon the integrity and proper nourishment of the rest of the cells of the body for life, being possessed of a much more delicate sensibility than the lower forms of cell life. As our bodies are composed of a network of millions of cells, it will be seen that, owing to this interdependence of cell life, and in order that the body may be in a state of health, all the cells which make up the various organs must perform their varied functions with unceasing regularity; that they must occupy their correct place, must be properly nourished, and finally, must be subjected to proper pressure. If these conditions are not fulfilled, the body at once gets out of order. If a blood-cell escapes from the blood-vessel, it acts as a foreign body, and a course of inflammation is set up to get rid of the intruder. If this condition happens in the lungs, as it often does, the blood-cells escaping into the meshes of the connective

tissue become the nucleus for a tubercle, and then one of three things happens. It may undergo a fatty degeneration, it may undergo a calcareous degeneration and become encapsulated with a covering of lime, in which state it can do no more mischief, or it may decay, and pus cells be formed, which are taken up by the vessels and carried all over the body, infecting it, and causing the patient to die in a few months of an inflammatory or "galloping" consumption. By far the most frequent cause of tubercle is, however, the inflammatory products of pneumonia, which undergo a caseous or cheesy metamorphosis, and are deposited in the pulmonary tissues.

These caseous masses may either undergo one of the forms of fatty or calcareous degeneration before alluded to, or they may break down and allow cavities to form; the establishment of such cavities and consumption of the lungs being much more frequently a result of chronic inflammation than of tubercular deposit. The blood-cells, or corpuscles exist, as it is well known, in the proportion of one white to about three hundred red corpuscles. If the white corpuscles increase in number unduly, as they may, from want of fresh air, sunlight, or exercise, they become very dangerous, as they move much more slowly than the red ones, and obstruct the vessels, and when the capillaries are thus obstructed the pressure may become great enough to rupture them, and permit the escape of a few blood globules into the tissues. If this happens in the lungs, as it sometimes does, it may be productive of consumption, as we have seen by the formation of tubercles. The calcification of the tubercle, a process which nature adopts in a spontaneous cure of phthisis, is what the physician should aim at in the cure of tubercles, it being merely an effort to second nature in her work, and if the disease has not progressed so far as to form large cavities in the lung, we may hope confidently for a radical cure. According to Dr. Green, of London, who has paid great attention to the microscopical examination of diseased lung tissue, "the structural changes met with in the lungs in phthisis are mainly of three kinds. 1st, an accumulation of large epithelial-like cells within the pulmonary alveoli; 2d, a thickening of the alveolar walls by a small-celled lymphoid tissue, together with, in most cases, the growth of a similar tissue around the minute bronchioles; and 3d, an increase in the interlobular connective tissue." "These changes are analogous to those which occur in the several forms of pulmonary inflammation, especially in catarrhal and interstitial pneumonia. The accumulation of epithelial-like cells within the alveoli in catarrhal pneumonia, with, in the more chronic cases, the ultimate thickening of the alveolar walls, and the increase in the interlobular connective tissue which characterizes the interstitial process, closely resembles the phthisical lesion." These anatomical or structural changes are due, according to Dr. Green, to differences in the intensity, in the duration, and in the mode of origin of the inflammatory process. Thus "in those cases in which the inflammatory processes are of slight intensity and long duration, the most marked structural change will consist in the development of a small-celled growth in the alveolar walls and in the interlobular tissue, a growth which tends to become developed into a fibroid structure; whereas in those cases in which the inflammation is of greater intensity, a proliferation of the large nucleated elements contained within the alveoli will constitute the more prominent part of the process." The former condition results in induration of the lung, and the latter in softening and caseation, the large

epithelial-like cells being incapable of further development, tending to undergo retrogressive changes. According to Dr. Green there are three different agencies concerned in the production of pulmonary phthisis. These are direct irritation, infection, and predisposition. The direct irritation he attributes to the successive attacks of catarrh of the bronchial mucous membrane, extending into the pulmonary alveoli, and causing inflammatory changes in them, giving rise to catarrhal pneumonia. The infection he describes as being identical with that causing general tuberculosis, the dissemination of the infective substance being effected by the blood and lymph streams or serous canals. The predisposition, he says, "appears to consist mainly in an abnormal susceptibility of the broncho-pulmonary tissues to the various kinds of injurious irritation." Dr. Green also holds that there are no pathological grounds for any subdivision of pulmonary phthisis into different varieties; "the variations in the anatomical characters of the lungs depending principally upon variations in the intensity and duration of the inflammatory processes which give rise to the pulmonary consolidation, and also upon the parts which primary irritation and infection play respectively in the causation of the disease."

There are two diametrically opposite forces which also operate in the production of consumption. The first consists in an overfilling or engorgement of the vessels of the lungs by blood, brought on by over-exertion, thereby causing some little capillary vessel or vessels to rupture, allowing the escape of perhaps not more than a teaspoonful of blood into the pulmonary tissue, which perhaps gives rise at the time to nothing more than a slight feeling of soreness in the chest, but which is the starting-point for a chronic pneumonia that generally proves incurable. The other and opposite condition consists in too little blood being sent to the lungs, as a result of want of proper exercise and close confinement, the upper part of the lungs being allowed gradually to collapse, and tubercles appearing as the circulation ceases to affect them. The peculiar anatomical formation of the lungs favors the formation of tubercles in the upper part of them, since, while to breathe with the lower lobes requires no exertion, a very full and deep inspiration is required to fill the lungs with air to their extreme points. Hence it is that tubercles appear at the apices of the lungs and spread downward, instead of from below upward.

There is another form of consumption known as acute miliary tuberculosis, which is the most fatal of all the varieties of consumption, and consists in the appearance of tubercles in the lungs and other organs of the body, being due in most cases, and it is claimed by some writers invariably, to the poisoning of the blood by the caseous products of pneumonia, or by pus-cells being introduced into the circulation, although it is claimed by Niemeyer that it sometimes appears as a primary disease, being unpreceded by caseous deposit. This disease runs an acute course, generally being developed at an advanced stage of consumption, the patient succumbing to it in a short time.

It has been noticed that in a great many cases there exists a very close relation between tuberculosis and insanity. Esquirol was the first to note this fact, and it has since been commented upon by Schroeder van der Kolk and Dr. Clouston. In some cases phthisis has preceded insanity, and in other cases, and probably in the majority of those in which a close relation seems to exist, the development of the two diseases has been nearly contemporaneous. It has been noticed that the forms of insanity complicated with phthisis exhibit a decided tendency to pass into dementia. Dr. Clous-

ton, in the "Journal of Mental Science," for April, 1863, gives a table showing the form of insanity in 282 patients who died with tubercular disease at the Royal Edinburgh Asylum. Acute mania 12, mania 15, monomania, 39, melancholia, 18, dementia, 153, general paralysis, 34. It will be noticed by the foregoing table that more than one-half of these cases passed into dementia, while on comparison of the tubercular with non-tubercular cases, it is shown that only one quarter of the latter class of cases were demented at death. It was noticed in all these cases that the acute stage of the insanity was of very short duration, and that the patients all manifested a decided tendency to pass rapidly into subacute mania and dementia. It has also been noticed that the prognosis as regards recovery of mental health is very unfavorable, and that apparent recoveries generally prove to be only remissions.

Etiology.—The first and most important cause of consumption is hereditary influence, which if not directly transmitting the disease to the child, yet beyond a doubt predisposes it to the acquisition of phthisis upon exposure to exciting causes. There is no doubt, however, that by proper hygienic influences we may succeed in warding off consumption from children who are hereditarily predisposed to it. Among the most potent of these means we may mention plenty of fresh air, sunlight, and muscular development. Another fruitful cause of consumption is the drunkenness of parents, which by entailing an impaired vitality, and also by depriving the children of such parents of proper food and clothing, directly predisposes them to affections of the lungs.

A sedentary life, in which it is not so much the overwork as the total want of muscular development, also often induces consumption in an otherwise healthy person. Examples of this may be found in all of the liberal professions which stimulate their followers to excessive mental labor, to the exclusion of muscular development, the want of which is almost universally noticed. Overwork in trades, by close confinement and the constant inhalation of irritating vapors and dust, and impure air from want of proper ventilation, often develops hereditary taints, that have been very likely unsuspected or forgotten. Certain trades are also much more likely than others to induce consumption, among which may be mentioned shoemaking, factory life, stone-cutting, and grinding of metals. In all of these trades the workmen are obliged to inhale continually various kinds of dust which irritate the lungs and cause obstruction and inflammation. In sewing-girls who are obliged to work hard and for many hours, with insufficient food, many cases are developed. Many physicians hold the opinion that marriage with a consumptive person induces consumption in an otherwise healthy person; and Dr. Henry J. Bowditch, of Boston, a noted authority on consumption, gives it as his opinion "that in some instances consumption may be promoted, if not caused by marriage, if imprudently contracted, and subsequently unwisely or incautiously consummated." It is a question of great importance whether or not consumption is caused by contagion or infection. Dr. Budd, of Bristol, England, claims that the dried sputa have spores in them of the "contagium" of phthisis, and thinks that they must be floating about in the atmosphere in which the consumptive is living, and attributes to this cause many cases of supposed hereditary transmission.

From the results of numerous experiments that have been made, there can no longer be any doubt that both the flesh and milk of diseased cows, if not submitted to a heat equal to that of boiling water, possess

the power of infecting both children and adults. Gerlach, Bollinger, Zürn, Leisering, Gunther, Klebs, Pétroff, and other experimenters, have all induced artificial tuberculosis by feeding tuberculous flesh and lungs, caseous lymphatic glands, etc., taken both from the human subject and from cattle and pigs affected with the disease. Nearly all the lower animals—cattle included—have been thus experimented upon, and it has been conclusively proved that they are all liable to acquire phthisis by the ingestion of diseased phthical food. Bollinger, Gerlach, and Klebs have also produced tuberculosis by giving animals milk from diseased cows, and it was found that the use of such milk *invariably* produced tuberculosis, which commenced as an intestinal catarrh, and then gave rise to mesenteric glandular tubercles. Afterward the liver and spleen became affected, and later the thoracic organs. Klebs insists upon the fact that the disease may be developed in children, in whom is no hereditary taint, through the medium of the milk of the nurse, or cows' milk, if taken from diseased animals. The majority of observers who have made a study of tubercle agree as to the histological identity of human tubercle with that occurring in the lower animals. Prof. Schüppel,* who has made a study of tubercle in general, and that of the bovine species in particular, has unquestionably established the absolute identity, in structure and development, of tubercle as appearing in the bovine species with tubercle in man.

The opinion is held by many physicians that by continual exposure, and particularly by living constantly in the same room, and sleeping with consumptive patients, the disease is communicated very frequently. A case came under my own notice, but a short time since, of a young lady, Miss F—, of Massachusetts, of fine physical development and perfect health, in whose family there was no taint whatever of consumption on either side, who contracted the disease by occupying the same sitting-room with a person who was dying with consumption, and who was expectorating constantly. There was no apparent cause, such as a sudden cold, that could be traced back; but she drooped, contracted a cough, and in less than a year had fallen a victim to this insidious disease. This is, we think, a case which goes far to prove the theory of contagion, and is by no means an unusual one, as many physicians can testify from their own experience. Quite a noted physician writes that he is thoroughly convinced that phthisis is frequently caused by contagion, and deserves to be placed in the same category with typhoid fever in this respect.

Consumption is often caused by a wet location, and particular care should be taken in selecting a residence to build on a dry, gravelly soil, in a situation not exposed to east winds and fogs. Plenty of fresh air, and sunshine are very essential to the mental and physical health of the inmates of any dwelling, and the sun should by all means be allowed to enter the house, and not be prevented by shade trees overhanging it, as is often the case.

Treatment.—The treatment of consumption by the ancients was as varied as we have seen their theories to have been, changing with each change of theory. The treatment of Hippocrates, Galen, and the oldest physicians, was to endeavor to dry up the ulcerations of the lungs by means of inhalations of tar, myrrh, etc., allay the cough by narcotics, and also to send their patients to dry places for change of climate. The remedies employed by the older physicians were almost exclusively of a vegetable character, al-

* Ueber die Identität der Tuberculose mit der Perlsucht.—Virchow's Archiv, Bd. 56, s. 38, 1872.

though occasionally they employed preparations of antimony, lead, and arsenic. Issues, setons, and artificial ulcers were also used to relieve the lungs. It was thought by some that the operation of an emetic was calculated to relieve the lungs of the specific principle that was supposed to exist, and accordingly the "Emetic cure" gained quite a reputation for a time. Prussic acid, sulphur, and sulphur baths, creasote, muriate of ammonia, etc., were all highly lauded, and in their turn have been discarded for other remedies. It was thought upon the discovery of iodine that it would prove a specific; but though accomplishing much good it was laid aside, as it did not fulfil the great expectations regarding it. Laennec held that consumption was incurable, but he was opposed by Broussais, who claimed that he could by bleeding extract the diseased blood, and then create new blood, and save his patients. But his failure only served to strengthen the idea advanced by Laennec of the absolute incurability of this disease.

As this idea gained prevalence, the habit was established of endeavoring to alleviate as far as possible the sufferings of the unhappy patients, by sending them to more favorable localities, where by change of air, diet, and scenery the disease would often become temporarily checked. Cod-liver oil obtained a wide reputation on account of the fact that iodine had been discovered in it. It was first used in Germany, then introduced by Bennett into England, and to this day is almost invariably prescribed by physicians when called upon to treat consumption, whatever may be the state of the patient for whom it is ordered. Its success was owing to the fact that the poorer classes in Europe, for whom it was prescribed in the dispensaries, had no means of procuring the flesh or fat of animals, owing to their extreme poverty, and the result attendant upon their immediate improvement upon the use of cod-liver oil gave the idea to many that it possessed most wonderful curative properties, and led them to prescribe it for all classes alike, when oftentimes nourishing diet of a different description would have been much more suitable. Fusel oil and alcohol have also been extensively used in phthisis, the former being productive of a great deal of harm in ruining the digestion of many of its victims, while the latter is, in our opinion, suited but to a very small minority of the sufferers from this disease. Those who have delicate skins and perspire freely, and with whom fatty articles do not agree, are oftentimes very much relieved by the use of alcohol; while for most other cases it is utterly inappropriate and generally hurtful.

Dr. Anstie, of London, a celebrated authority upon this question, gives the following as his opinion: "We are justified in believing that when alcohol reduces temperature and the diastolic pulse, and fails to pass away in notable quantities by the kidneys, it always does good, but that the slightest degree of narcotic action of alcohol is harmful." Out of 210 answers received to the question, whether consumption was prevented by the free use of spiritous liquors, 113, or 53.8 per cent. answered in the negative, while 3 per cent. answered that its progress might be retarded. It will be seen, therefore, that a large majority of our best educated physicians unite in the condemnation of the treatment of consumption by a free use of alcohol.

The treatment of the ancients by inhalation was revived by Sales-Girons at the baths of Pierrefonds, a watering-place near Compiègne. Sales-Girons read a paper before the Hydrological Academy of Paris, on December 8th, 1856. In this paper he described his

establishment, and contended that the spray inhaled penetrated deeply into the respiratory tract. Sales-Girons received from the Academy a silver medal in recognition of his valuable services in adding to our therapeutical resources. When we recollect that the mucous membrane of the respiratory organs possesses a much greater capacity for absorption than that of the stomach, being much more delicate, and that in many cases it is very desirable that the medicines should not be subjected to the chemical action of the gastric juice, we see that in many cases inhalation is to be preferred to internal treatment. The medicines inhaled come into close contact with the blood in its most vital state, and are consequently more thoroughly absorbed into the circulation than when they are obliged to make the circuit of the blood before reaching the lungs.

The proper treatment of consumption is a very difficult task, as it requires great tact and constant attention to the wants of a patient to keep him in good physical condition. We would insist primarily upon the removal of all mental causes calculated to make the patient despondent and unhappy, as without this all attempts at medication will be in vain. The next most important thing is to place the patient where he can have plenty of fresh air, sunlight, and as much muscular exercise as he can bear without fatiguing him too much. If we can by such means induce a good appetite and digestion, the patient is sure to improve, if not to recover. The diet must be carefully attended to, and nothing calculated to injure the digestion be allowed under any circumstances. Milk, which is one of the articles of food that makes good blood, may and should be freely used, and also bread, which should always be cold. Wheat, beans, and fish, which contain phosphorus and build up the nervous system, should also be used, while the growth of the body requires the albuminous, carbonaceous, and fibrous compounds that are obtained by a diet of meat, eggs, milk, and vegetables; ripe fruits are also very wholesome. Pastry, hot tea and coffee, and excess of drink with meals are to be avoided in all instances. When there is a constipated condition of the bowels, we should endeavor to regulate them by diet rather than by medication, if possible, and the use of cathartics should be forbidden. To this end the food should be thoroughly masticated before being swallowed, and ripe fruits and berries may be used, with coarse brown bread, or Graham bread, or cracked wheat eaten with syrup.

The patient should pay great attention to the skin, and salt baths (a solution of rock salt) with subsequent friction night and morning with coarse Turkish towels will have a very decided effect for good if regularly used and persisted in. The baths should be sponge-baths, as many persons with phthisis are unable to stand the shock incident upon getting into a bathtub of cold water, as there is not sufficient reaction, owing to a lowered vitality in such patients. Children predisposed to consumption should wear flannel next to the skin constantly, summer and winter, the weight and thickness of it being adapted to the seasons. A radical change of climate may oftentimes be experienced by moving, or going for a time, for a short distance only, by which change a high and dry location may be substituted for a low, wet, and marshy one, and whenever this is practicable it should be accomplished, as a change of residence for a few months at the outset of this disease will often check it and prevent the formation of tuberculous cavities in the lungs, which must necessarily, if progressing to any extent, destroy the life of the patient. The medical profes-

sion since Laennec have come to believe that consumption is absolutely incurable; but here and there we find one who believes in the spontaneous cure of phthisis. Prof. Bennett, of Edinburgh, gives it as his opinion "that of no disease was evidence of a spontaneous cure more frequent than of pulmonary phthisis." As Bennett shows very clearly that tubercles heal by "calcareous degeneration," the best method of treatment seems to be to imitate as nearly as possible the process which nature adopts in a spontaneous cure of phthisis, and endeavor to promote the calcification of tubercles by introducing into the blood the salts of lime, and then get a deposit of lime around the tubercle. In order to do this we perfect the process of respiration by strengthening the muscles of the chest, which can be accomplished by gentle muscular exercises and forced inspiration and expiration, taking as long as possible for inspiration, and then expiring slowly and steadily, and in this way repeating this exercise daily in the open air we shall find great improvement in the respiratory powers of the patient. If no large cavities exist, we can by such means as the above, if we can place the patient under proper hygienic influences, almost invariably arrest the progress of consumption. The more that can be accomplished by introducing such medicines as iron, etc., with the food, the better, as we run much less risk of disturbing the patient's digestion. Another very important object is to secure a good sleep to the patient, who is generally restless and uneasy at night, and to this end the muscular exercise that has been spoken of, together with the cold salt baths, with friction over the whole surface of the body before retiring, as well as upon rising in the morning, will generally tire the patient sufficiently to secure him a good sound night's rest. Tonics, such as iron and quinine, are often required, and in cases in which their use is indicated rapid improvement is generally found to follow their employment. Cod-liver oil is particularly indicated in patients of a strumous diathesis, and may be given in connection with iodine and iron. The objectionable taste of the oil may be overcome by the use of the following formula, which has the advantage of combining phosphorus and cod-liver oil in a pleasant emulsion. The use of the phosphoric acid will often overcome the nervous exhaustion and depression under which the patient is laboring, and at the same time assist the appetite and digestion. The writer is in the habit of prescribing it, and invariably with the happiest results, patients taking it readily who could not bear the plain cod-liver oil at all.

Rub the eggs up in a mortar, adding the oil spoonful by spoonful. Last of all add the phosphoric acid.

Inhalation of compressed air, oxygen gas, and the vapor of iodine may all be used with advantage in certain cases. The inhalations of compressed air are more particularly useful in the first stages of phthisis, their action being to supply the blood with oxygen, and also to stimulate the appetite and increase the powers of digestion. By the application of compressed air, there is a considerable increase of the negative pressure of inspiration, and of the positive pressure of

expiration, which results in an increase in power of the muscles of inspiration, and also in a reduction of the circulation and of the animal heat. Inhalation of oxygen gas may be used with advantage in phthisis in assisting the lungs in the decarbonization of the blood in a manner that does not force the lungs to perform such an exhausting number of respirations as would otherwise be necessary in order to supply the body with the requisite amount of oxygen. Its use is contra-indicated in all inflammatory states of the lungs and respiratory organs.

Inhalations of the vapor of iodine are of the greatest efficacy in the treatment of phthisis; producing in nearly every case decided amelioration of the symptoms of the disease, while in many cases tubercles have disappeared and tuberculous cavities healed under this treatment. These inhalations have been tried and their value attested by many well-known authorities, among whom may be mentioned Laennec, Lugol, Baudelocque, Sir James Murray, Sir Charles Scudamore, and many others. M. Piorry, of France, says: "In many cases these inhalations have been followed by a diminution in extent of the indurated parts surrounding tuberculous deposits, and the amelioration of the general symptoms," and he reports several cases which were apparently cured by these inhalations. The method which the writer employs and prefers is, to attach to a steam atomizer a rubber tubing, which is attached to the little tube on the boiler from which the steam issues, and at the other extremity of the tubing is attached a hard-rubber face-shield, in which is a chamber for holding a sponge, which is saturated to the desired extent with the tincture of iodine. The steam is then passed through the tubing by the operation of the atomizer, and the patient inhales the vapor from the face-shield.

If this vapor should at any time prove to be irritating to the respiratory tract, a few drops of the tincture of conium may be added to the iodine at the time of inhalation. Soothing inhalations, by which means the medicines inhaled are nebulized, or converted into a fine spray, are of great service in checking the troublesome cough which harasses the patient night and day, by allaying the irritation which excites cough. Among the most useful of these medicines for inhalation may be mentioned muriate of ammonia, chloride of sodium, tinct. conium, glycerole of tannin, tinct. of opium, and tar water. The use of the sesquichloride of iron in inhalations, in the form of spray, has been highly praised by Biegler, the strength employed being from five to twenty-five minims to the ounce of water.

The inhalation of the vapor of creasote has sometimes been of service in checking secretion, allaying irritation, and arresting expectoration. It is impossible, however, to lay down a definite plan of treatment suited to all cases alike, as no two cases will be found to present the same indications, and each individual case demands the utmost care and attention to age, sex, and idiosyncrasies that the practitioner can bring to bear upon it, if he hopes to effect a cure. In diagnosing a case of phthisis, the sputa should invariably be subjected to a careful microscopic examination, as the presence of elastic fibres in the expectoration, which come from the walls of the air-vesicles, are pathognomonic of phthisis, and we are then enabled to decide oftentimes as to the existence of disease where the physical signs may be so slight as to lead us to doubt the existence of consumption. Microscopic examination of the sputa also reveals to us, in phthisis, pus corpuscles and tubercle corpuscles. In searching for elastic fibres, any little grayish masses in the sputa

should be picked carefully to pieces with needles and particularly examined.

Finally, as it will be found much easier to prevent the acquisition of consumption by prophylactic measures than to arrest it after its development, everything calculated to cause an afflux of blood to the lungs or to the respiratory tract should be avoided, and persons in whom a tendency to consumption is suspected should not be allowed to inhale an atmosphere impregnated with smoke or dust, or which is either very hot or very cold, and they should also avoid great exertion, such as immoderate running, dancing, or singing, and also the dampening of the feet at nightfall. If possible, the northern winters should be avoided, and the patient sent where he can spend his time in the open air, without the risk of taking cold, which is the principal good resulting from a change of climate. It is encouraging to find that during the past twelve or fifteen years the mortality from consumption has been steadily decreasing, owing to the improved views that have been formed regarding its treatment, and this fact gives ground to hope for a still greater diminution in the mortality for the future.

AN APPARATUS FOR SUPPORTING THE PATIENT WHILE APPLYING PLASTER-OF-PARIS IN THE TREATMENT OF FRACTURED FEMUR.

By P. A. HARRIS, M.D.,

DOVER, NEW JERSEY.

PRIOR to the month of June, 1873, I treated fracture of the femur by the very fashionable plaster-of-Paris bandage. Although I had had considerable experience in the use of this desirable dressing, yet I always found it a difficult task to apply a good permanent dressing to a fracture above the knee, according to the most approved methods of operating. My experience began with the use of the perineal iron stanchion, bent over at the top with a hook, from which a strap or wire passed around the loins, and served to support the patient several inches above the

right thigh, leg, and loin. This man was recovering from a compound comminuted fracture of the neck, trochanters, and upper one-fourth of the femur, on whom I had performed the operation of excision of the head, neck, and fragments of bone seven weeks previous.

It served a good purpose, supporting the patient in a horizontal position, except the injured leg, which must always be held by an assistant during the application of the bandage, leaving nothing in the way of the operator.

The accompanying illustration represents the apparatus. It is over five feet long, two feet wide, and ten inches high. It consists of a long and short side, each being made up of two boards of equal width, placed one on the other edgewise, and held together by two bolts provided with thumb screws, which also serve to fasten the tenons of the two cross blocks, thus connecting the sides together; of six slats forming the body-rest, placed across and secured at either end by a screw; of a third cross-block, very short, which serves to support the rest on which the sound leg is placed. This short cross-block has two tenons, which pass through mortises in the long side, and are held in place by a wooden pin.

The sound leg-rest is secured to the long side by a screw, and to the short cross-block in like manner. It is provided with a series of holes to adapt it to the length of the patient. The half circle-like opening in the long side, between the sound leg-rest and the body-rest, corresponds to that portion of the body around which the dressing must be carried to form the girdle. This opening is ten inches long, its maximum depth being six and one-half inches.

A very short perineal band* attached to two broad straps of thin leather will furnish counter-extension. Secure one end to a slat near the head of the apparatus, let it pass down over the slats forming the body-rest, between the thighs, up over the body and shoulders, and fastened again to one of the slats near the head. A part of the apparatus which remains to be described is the folding-rest for supporting the injured leg until ready for operation. It consists of two boards, one much thinner than the other, held together by a screw

which allows the part forming the leg-rest to be abducted to any extent from the sound limb. When removed from its place, as it will be while the plaster-dressing is being applied, it can be folded together—hence named folding-rest. At the end of the under thicker portion of the folding-rest is a tenon which is made to pass between

bed during the application of the bandage. While this method was better than any other I knew of at that time, yet it failed, in my judgment, to accomplish all that was necessary in a successful application of the bandage. I was so confirmed in the belief there was still room for improvement, that I resolved never again to attempt the treatment of fracture of the femur by the plaster bandage without a different, if not a better, method of supporting my patient.

I immediately devised and had constructed the apparatus I am about to describe, which I used for the first time in October following, for supporting a man while a plaster-of-Paris bandage was applied to the

the slats forming the body-rest, and the upper edge of the first cross-block; it is provided with a spring which prevents it from being pushed out of the mortise. The folding-rest is valuable, particularly as a support for the injured limb during the administration of an anæsthetic. If the limb be firmly bandaged to it, it will prevent, to a large extent, the injury so often done to the soft parts by the violent, uncontrollable, muscular efforts so common in the beginning of anæsthesia.

The apparatus is so constructed that it can be

* Not shown in cut.

quickly set for either leg, or changed from one to the other.

To change it from left to right, or *vice versa*, unscrew the four thumb-screws, remove the bolts, and change the under half of side supports each for the other. Insert the four bolts, and tighten the thumb-screws. Then remove the two screws which secure the sound-leg-rest, and withdraw the pin from the tenons at the end of short cross-block. Remove short cross-block, insert from the opposite side, and secure it with pin. Turn the sound leg-rest the other side up, and fasten by the two screws as before. When this is done, the folding-rest can be introduced as before; in fact, every part of the apparatus remains the same, except it has been changed from left to right, or *vice versa*. To render it more portable, I have constructed it so that by removing the four bolts it can be folded together and made to occupy about one-third the space.

Three minutes will suffice to set up the apparatus, or change it from side to side.

Directions.—Before placing the patient on the apparatus, let the body-rest be covered with several folds of a blanket or coverlet, and provided with a pillow. The leg-rest should also be padded by doubling a small blanket over it. Let one end of the strap attached to the perineal band be buckled on the first slat at the head of the body-rest, and carried down over the centre of the rest. Place the patient on the apparatus so that part of the body and pelvis, around which the bandage must be carried, will correspond to the vacant space between the leg and body-rest. Continue the counter-extending band over the perineum and abdomen, and secure its strap to the slat at the head of the apparatus. Secure the sound leg to its rest by a few turns of a roller passed round the leg, under the rest, and through the slats near the upper edge of the long side. The patient's body and sound leg are now supported on a common plane several inches above the bed or table on which the apparatus rests. Every part to which the dressing should be applied is accessible to the hand of the operator. The sound leg-rest may be abducted to any distance compatible with a successful appliance of the bandage. The injured leg, of course, must be supported by an assistant, aided perhaps by the compound pulleys so often required for extension. Abduction to much extent causes the girdle to fit poorly. When the dressing is hard enough to warrant us in discontinuing the extension, the straps attached to the perineal band may be drawn out from under the girdle, the bandage removed from the sound leg, and the patient transferred to the bed.

I cannot here consider the comparative merits of plaster-of-Paris, or the so-called "permanent dressings," and the "movable apparatus." We may hope, however, that with the approved methods of operating we will discover peculiar merits in permanent dressings, and thus make them as applicable to the treatment of fracture of the femur as they have proved in fractures of the leg or arm. In either case a certain amount of experience is necessary in order to make a decent bandage, and if there is a general applicability about "permanent dressings" which we find in no one movable apparatus, why should we not make the most of them, and determine if they still have not claims of superiority over other methods in the treatment of fracture of the femur.

M. URITZ has been nominated Professor of Organic Chemistry in the Academy of Sciences of Paris.

A CASE OF TRAUMATIC VENTRAL HERNIA.

By R. GEORGE GLASS, M.D.,

HOUSE-SURGEON, BELLEVUE HOSPITAL.

E. S., fifty-eight years of age, was admitted into Bellevue Hospital, May 25th, 1875, and gave the following history:—

He was working in a factory, filing metallic plates, and found it very convenient when at work to rest the material to be worked on the bench, and hold it firmly by pressing against it with his abdomen. This practice (he being a new hand and working hard) made him very tender and sore in the abdominal region. In the month of October, 1874—shortly after beginning this work—he found a circumscribed point of tenderness in the abdomen, midway between the umbilicus and pubes, and in the median line. The following day it became worse, and in a few days ended in an abscess, which was opened by a physician. With the pus which followed came a few inches of intestine. At the end of six weeks he had recovered, and resumed work at his trade.

On the morning of the day of admission he was working on a machine run by hand. Projecting from the front of this machine, about three feet from the floor, was a dull piece of iron, in the form of a spike. Against this the patient, while suddenly leaning over, struck his abdomen, causing a rupture of the walls, and a protrusion of intestines.

On admission, patient suffered considerably from shock and felt very weak. Before being admitted to this hospital, several attempts had been made at reduction of the hernia, without success—once under the influence of an anæsthetic. He had also taken a hot bath. Examination of abdominal walls showed a loop of intestines, thirty-five or forty inches long, protruding from an opening about an inch and a half in length. This opening has taken place in the cicatricial tissue, in the site of an old abscess, which extends from the umbilicus downwards, in the median line, to the pubes. The wound is situated lying in a vertical direction, and occupying a position half-way between these two points. The intestine is deeply congested; and at one point, near the extremity of the loop, there is a dark discoloration, which looks very much like gangrene. Bloody serum exudes from the surface of the intestine.

The patient was anæsthetized, and, after the gut was washed, an attempt was made to reduce, which was ineffectual, owing to the swollen condition of the intestines and the cicatricial rigidity at the opening. The upper part of the wound was made larger by the introduction of a hernia knife—care being taken to thrust the finger in between the peritoneum and abdominal wall, so as to avoid injury to the former—making an incision about an inch long; and, after stretching the wound with the fingers, the hernia was reduced. The wound was then closed by silver wire sutures and the patient kept moderately under the influence of opium for four or five days. He was then discharged cured in eighteen days, with orders to wear an abdominal support.

M. RANVIER has been appointed to fill the new Chair of General Anatomy, which has been established in the College of France, at Paris.

DR. LIEBREICH, of Berlin, has received a diploma of honor from the Vienna Exhibition for his discoveries of the properties of chloral.

Progress of Medical Science.

TABETIC AFFECTIONS OF THE JOINTS.—M. Charcot recently presented specimens before the Society of Biology, illustrative of a peculiar disease of the joints, which he denominates tabe-arthropathy. The disease in the hip is characterized by diminution in volume and atrophy of the head of the femur, and an appearance as though the bone had been worn away. Apparently such changes had taken place in the bone-structure that it became incapable of supporting the physiological pressure. Spontaneous luxation of the joint had taken place in consequence of these changes. The speaker believed that as much as half of the so-called spontaneous luxations were due to similar alterations in the structure of the joint. Opposite the head of the atrophied femur "osseous stalactites" had formed on the iliac bone, indicating an inflammatory process "analogous to that observed in dry arthritis." Similar lesions were found in the shoulder-joint. In one specimen the alteration was seen to consist entirely in a wearing away of the head of the humerus; there was no trace of any inflammatory action. According to Charcot, the pathology of the affection was obscure, but there could be no doubt of its dependence upon lesions of the central nervous system. He claims to have met with more than fifty cases of the disease, and believes that it is not uncommon.—*Gazette Médicale de Paris*, Aug. 7, 1875.

INSUFFLATION IN INTESTINAL OBSTRUCTION.—Dr. Brun, in a communication to the *Journal de Médecine* of last month, describes a case of intestinal obstruction, due to the ingestion of large quantities of service fruit, which was successfully relieved by means of J. Wood's method of insufflation of air. The difficulty had lasted for four days, and had resisted all the ordinary methods of treatment. Moreover, the procedure recommended by Taliaferro of injecting into the bowels bicarbonate of soda and citric acid separately, for the purpose of liberating gas in the intestines and distending the canal, had been tried ineffectually. The patient was evidently sinking; the pulse was very feeble, and there was stercoraceous vomiting. An œsophageal sound was introduced into the rectum, and to the external extremity the nozzle of an ordinary bellows was attached. Air was then injected till the abdomen had increased markedly in volume. The first attempt, however, was unsuccessful. It was repeated, and the insufflation continued until considerable abdominal tension was produced, and respiration was rendered difficult. In the course of an hour dejections began and the patient recovered.

INFLUENCE OF COMPRESSED AIR UPON FERMENTATIONS.—M. P. Bert has ascertained that compressed air has the property of delaying or arresting (depending upon the degree of pressure) putrefaction, and the oxidations which accompany it. Thus, a bit of muscle, subjected during five days to a tension of oxygen corresponding to twenty-three atmospheres of air, did not present any odor, and had only consumed 380 cubic centimetres of oxygen. A piece of the same weight, exposed to similar conditions, excepting that the pressure remained normal, consumed 1,185 cubic centimetres, and emitted a very foul odor. On increasing the pressure, the oxidations were completely arrested. The meat thus exposed to compressed air

preserved its general appearance, its firmness, and histological structure; the color was slightly changed. The flavor of mutton cutlets, preserved for one month in oxygen, compressed to a degree corresponding to forty-four atmospheres of air, was slightly insipid. With regard to the diastasic or catalytic fermentations, that is, those produced by the saliva, the pancreatic juice, the vegetable diastase, pepsin, etc., M. Bert has ascertained that they are not modified by compression of the air. Furthermore, on their removal from the air these substances may be enclosed in vessels and preserve their properties indefinitely without alteration. This is, therefore, a certain method of preserving indefinitely, in their natural state, such matters as the juice prepared by bruising the salivary and pancreatic glands, or from the mucous lining of the stomach of slaughtered animals, and thus might be rendered of great service to therapeutics.—*Journal de Médecine*, Aug., 1875.

BILIARY CALCULI EXTRACTED THROUGH THE ABDOMINAL WALLS.—M. Brousson, of Nîmes, describes the following case: A patient was suffering from a painful, ill-defined tumor, situated in the right flank, between the spine of the ileum and umbilicus. The tumor was taken to be a suppurating ovary, and was opened with the caustic Vienna-paste. The tumor was found to be due to an accumulation of biliary calculi, of which no less than forty were removed. In three months the patient had recovered.—*Journal de Médecine*, Aug., 1875.

PETIT MAL.—A case of this disease was reported in the *Peninsular Journal of Medicine* of last month (August), by Dr. J. J. Mulheron, and presents the following points of interest: The patient was a boy, ten years old; the attacks of the disease had commenced two years before, and were apparently in the first instance produced by fright. They had gradually increased in frequency, and when the patient was first seen by Mulheron they occurred from six to twenty times daily, and were confined mainly to the morning hours. The character of the seizures is thus described: Just previous to the attack there was a slight defect in the co-ordination of the muscular movements. The attacks were not characterized by the slightest degree of muscular rigidity, but partook more of the nature of a sudden collapse, the patient squatting as he stood, and the body being perfectly limp. Sometimes the patient would fall, but on reaching the ground would immediately regain his feet. There was no frothing at the mouth or injury to the tongue, nor was the attack preceded by the epileptic scream or followed by coma. With the milder attacks the head would fall suddenly forward, or the flexion would occur in the lumbar region. During these attacks the patient retained his feet, though with much apparent difficulty.

The treatment pursued in this case proved remarkably successful. It consisted in putting the patient upon Brown-Séquard's epileptic formula, to which was added ten drops of the fluid extract of ergot at each dose, and the medicine was repeated every three hours. The ergot was suggested by the heat and congestion of the head observed during the attacks. In addition to this a blister was raised as nearly as possible over the region of the medulla oblongata—this measure having for its indication the irregular muscular movements which preceded the attacks. The next day the seizures were lessened decidedly, both in frequency and in severity. Improvement progressed rapidly, and in a few days the attacks had ceased entirely.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

A FLOATING HOSPITAL FOR CHILDREN.

THE exertions of the St. John's Guild to provide, during the past summer, for the sick and destitute children, are worthy of great praise. Although so far the success of the summer excursions shows how warmly the philanthropic heart is interested in such movements, we hardly think that the end reached, at least in a sanitary point of view, is as satisfactory as it would have been had somewhat different means been employed. Of course we have no statistics to support the opinion that these excursions were a toil of pleasure and a positive discomfort to many that went to them, but we think we are warranted on general principles in holding such a view. The popularity of these picnics is a matter of congratulation, not so much in the view of what has actually been accomplished, as what we have reason to expect in the future—a beginning of the bestowal of more lasting sanitary privileges upon a class of sufferers which heretofore have been so much neglected. The profession will willingly give the credit to the indefatigable managers of the Guild for initiating a great reform, and will look to them for the necessary changes in the plan of management which will realize the consummation of a long-deferred hope.

Every one admits that fresh sea air is of the greatest benefit in the treatment of many, if not all, of the infantile diseases which prevail during the summer months in our large cities. The difficulty, however, with the present arrangement is, that the sick ones are not subjected long enough to its influences to do much good, or, in other words, the good which they may gain from it is not counterbalanced by the toil and bustle which attends a short and hurried trip down the Bay or up the Hudson. We will not venture to say how many feeble children are positively damaged by being taken to and from their homes for this purpose, who would be permanently benefited by a residence of a week or more upon a floating hospital.

The question presents itself in this connection as to the feasibility of establishing such a sanitarium under the auspices of those managers who have been so active in popularizing the summer excursions. It is true the benefits would be limited to a much fewer number, but in consideration of the ultimate good to be gained we believe it would be warrantable. The St. John's Guild already have a barge well suited for hospital purposes, at least it can be made so with very little outlay. During the summer months this vessel could be anchored at a convenient distance from the city, and the details of regulation could be such as to make it one of the most useful and best patronized children's hospitals in the country. There is no question that the profession would support it by every influence in its power, and the time would not be far distant when there would be a call for a number of similar establishments; whilst the real good which would be accomplished would, in the end, secure legislative aid in the shape of some State appropriation. The time for agitating the measure seems to have arrived, and it is to be hoped that the officers of the Guild will take the matter into serious consideration, and direct the popular current of sympathy for their undertaking into a channel of the greatest possible usefulness to the poor needy sufferers.

THE LARGE-FEE SYSTEM.

A CORRESPONDENT, in another column, asks a very pertinent question in reference to the large-fee system which prevails in our city. There is no doubting the fact that one of the rewards of pre-eminence in any profession is a proportionately large fee for services rendered. This is in the main as it should be, and is in keeping with the general principle in every calling which places a premium upon skilled labor. It, however, is no reason why some men of reputation should take advantage of their position by making exorbitant charges. A patient, when he calls upon such a gentleman, naturally expects to pay a larger bill than he would to an ordinary practitioner, but that such charges should have some reasonable limit is beyond a question. The fact that such is not the case places not only the patient, but the physician who serves him, in a very disagreeable position. We regret to say that cases similar to those alluded to by our correspondent have come to our notice, proving the utility of the establishment of some such plan as is adopted by the leading consulting physicians of London and Paris. Nothing, in our opinion, is calculated to degrade the profession more effectually in the eyes of the public than the charge that the leading men in its ranks are willing to stoop to extortion. Happily, however, cases of this sort are not common.

HOMOEOPATHY IN MICHIGAN UNIVERSITY.

IN another column will be found a letter by Dr. Gerish, which will be read by all who are interested in

the discussion concerning the homœopathic trouble in the University of Michigan. As Dr. Gerrish was for a time a teacher in the institution, and is well informed concerning the subject of which he speaks, his opinions are entitled to great respect.

THE LECTURES IN OUR MEDICAL COLLEGES.

WE have given considerable space in the present number to a tabulated account of the lectures to be delivered in some of the leading medical colleges, trusting that it may be of value to such as may desire to be informed of what is to be done the coming winter in these schools.

Correspondence.

LARGE-FEE SYSTEM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In THE RECORD of July 31st you gave us an editorial upon the "Small-Fee System," in the sentiments of which I express my hearty concurrence. Now, may I ask the favor that you will state your opinions upon the "Large-Fee System," which, in my opinion, is a theme of much higher interest as regards the welfare of our common profession. It is a well-known fact that New York physicians are in the habit of charging more for their services (both in ordinary practice as well as in consultations) than physicians in any other sections of our country. I presume that you have often heard complaints of exorbitant fees demanded both from our own citizens and from those temporarily sojourning with us. If I have occasion to consult Sir William Ferguson, Sir James Paget, or Sir William Gull, in London, I know what amount of "honorarium" will be demanded (for ordinary consultations, one guinea; for a written opinion, two guineas), and I go prepared with the requisite amount. In Paris the same usage prevails. But if I send a patient to consult some of our distinguished confrères I can form no idea beforehand of the amount to be demanded of him; and I know that in some cases the "honorarium" is regarded as exceedingly large in consideration of the services rendered. When I hear patients and the executors of estates complaining of such excessive charges, I am tempted to ask myself the question, "Has the practice of medicine and surgery become a mere money-making pursuit, or is it the same self-denying, high-toned, and charitable profession as in bygone years?"

"RECTUS."

HYDROPHOBIA EXTRAORDINARY.—A rather incredible story comes from Lucknow, India, where several persons are said to have been attacked with hydrophobia in consequence of eating peaches plucked from a tree, at the root of which dead dogs had been buried. The virus of hydrophobia, says *The Indian Daily News*, had first impregnated the soil, next the sap of the tree, and subsequently transmitted itself to the fruit. The patients all recovered, so that no opportunity was presented for examining for "hydrophobic degeneration" of the medulla.

HOMŒOPATHY IN THE UNIVERSITY OF MICHIGAN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—That a great deal of interest is felt by the profession in the homœopathic question in the University of Michigan is clearly shown by the number of articles concerning it which have appeared in various journals. The matter has not as yet, however, as it seems to me, been so presented in THE RECORD as to convey nearly correct impressions to the minds of the very large body of medical men who derive their chief or only information on this point from your journal; and, with your permission, I will attempt a brief and plain statement of the relations between the homœopaths and the University. In doing this I am actuated simply by a desire to help the profession to the exact truth in the premises, in order that they may draw intelligent and just conclusions respecting an affair which concerns not merely western physicians, but all medical men everywhere. It may be well to state that my knowledge of the facts in the case has been derived from original and authentic sources, and not from flying rumors and unreliable reports.

More than twenty years ago the homœopaths in Michigan began making efforts to introduce the teaching of their doctrines into the State University. They effected the enactment of a law, in 1855, requiring the appointment of two homœopathic professors in the medical department; but the regents, claiming "that the law was an infringement upon the rights and prerogatives of the board," and plainly seeing that its execution would seriously damage, perhaps practically destroy, the growing and promising school, positively refused to comply with its provisions. The homœopaths, however, persisted in their endeavors, and in 1873 the Legislature re-enacted the previous law. Again the regents declined to conform to its requirements, and the matter was carried into the courts. The supreme tribunal of the State refused to grant a mandamus compelling the regents to obey the law, and thereby substantially confirmed their action. Though maintaining this position of antagonism to the Legislature, the regents declared that they did so in no spirit of factious opposition, but because they believed the true and best interests of the University demanded it; and they expressed "a willingness to take official charge of an independent school of homœopathy and connect it with the University, whenever the means should be provided for the payment of its professors." In 1874 the court again refused to interfere, saying it saw no reason to change the opinion formerly given. At this the friends of the University breathed more freely; for it seemed that the homœopathic difficulty was settled, as long, at all events, as no change took place in the composition of the supreme bench. But the last Legislature revived the matter, though in a somewhat different form. It passed "a bill for the establishment of a homœopathic medical department of the University of Michigan," the text of which was published in THE RECORD of the 15th of May. This bill appropriates six thousand dollars annually, which must be used exclusively for the benefit of the new department. It is worthy of note that while this is a display of legislative generosity such as never was made to the regular school, with all its claims upon the gratitude of the people, the sum appropriated is less than half the amount paid yearly to the teachers in the old department, and is consequently utterly insufficient to defray the ordinary expenses of a medical school with as many professors and an equally

ong term. In order, therefore, that the homœopathic school, if independently and as completely equipped with instructors as the old school, might not be a financially embarrassing addition to the already distressed University, it should have about two hundred paying students, a number which nobody, I think, has any expectation of seeing there; so that the regents, if adhering firmly to the spirit of their resolutions of 1873, could hardly find in this legislative action alone an adequate reason for any response different from that previously given. Whether or not the board would have accepted the grant and the accompanying obligations if liberal and much-needed appropriations for other purposes in the University had not hinged upon their acceptance, it is unnecessary to discuss here and now. The fact is, they agreed to take the money and its attached responsibilities.

Two plans for the details of the expenditure were brought prominently forward. One, proposed by Professor Sager, looked to the establishment of the homœopathic school on a distinct and independent basis. As has just been stated, the six thousand dollars and the fees of the homœopathic students would not cover the expenses of a school with a six months' course and as many teachers as the regular school has; but "by adopting a four months' course, which is the usual period in other homœopathic colleges, it would be entirely within the limits of practicability to appoint a full corps of six professors, and give to each member one thousand dollars, without any disparagement to the new faculty. They would thus avoid the otherwise inevitable collisions, the strifes, and distracting doubts among students and faculties, arising from opposite teachings, and relieve the faculty of the old school of the grave responsibility of employing their talents and experience as teachers, and yielding to their opponents the prestige of an old and well-established regular school, and of thus directly promoting a school of dogmatism, which, in common with nine-tenths of the profession the world over, they believe to be false in principle and prejudicial to the best interests of humanity." This proposition seems to have received little attention and no favor, presumably on account of homœopathic opposition.

The other plan, and that adopted by the regents, was to establish a homœopathic college with a faculty consisting of the president of the University, as official head, and two professors, one to teach the theory and practice of medicine, the other materia medica and therapeutics. The announcement says: "To gain instruction in general chemistry, anatomy, organic and applied chemistry, physiology, ophthalmology, otology and practical anatomy, surgery, obstetrics and diseases of women and children," the homœopathic students "will attend the lectures on those subjects in the 'Department of Medicine and Surgery.' While in attendance on such lectures they shall be entitled to all the privileges accorded to students in said department, and shall conform to all requirements of said department, so far as they apply to the branches which they pursue." Thus, since the same professor in the regular school teaches materia medica and physiology, it appears that the homœopathic students will receive instruction from every member of the old faculty, excepting only the professor of practice. They receive the sacred promise of an equal participation in all the facilities afforded by the University, which includes the daily lecture-room quizzes of the instructors in the old department. These professors will likewise examine them in the studies of their respective chairs at the end of the course, as they do the regular candidates for the degree, and give certificates of their pro-

iciency, which will be used in determining their fitness to practise medicine homœopathically.

If this condition of affairs is accurately described by the words of your official correspondent, in the issue of the 24th of July, when he speaks of the schools as "distinct and independent departments of the University," then must most intelligent members of our profession learn a new definition of the word "independent." It is true that no professorial association in faculty meetings is required by this arrangement, as by that law which excited the regents to a twenty years' war with the legislature; but to what extent are the most of the faculty giving less aid and comfort to their old enemy than if the act of 1873 had been enforced and they had retained their chairs? If the regular school were to suspend operations altogether, what would become of the new and "independent" school, with its "faculty" of two professors and a non-medical figure-head? The answers to these queries will give one an idea of the actual, practical relation of the two schools, and the necessary dependence of one upon the other.

Affairs being in this state, it is a matter of surprise and regret to very many of the most thoughtful men in the profession that the members of the old faculty should not resign their professorships. Those who know them well, however much deploring their decision, are willing to believe that they retain their places in obedience to a conviction that the present arrangement is the worst possible for homœopathy, and will result in its downfall. In contrast to their course, the venerable Dr. Sager, emeritus professor of obstetrics, gynecology, and pædiatrics, who has for years been dean of the medical faculty, believing that the plan adopted compromised the professional honor of the faculty, promptly resigned his office, for which act he has been roundly abused in certain quarters, and as cordially applauded by most of those who have appreciated the precise situation. Professor Gross, in a letter to Professor Sager, commending his determined attitude, remarks that, in his opinion, "The American Medical Association and all our colleges would unquestionably place the medical department of your University under the ban, and cease to recognize your pupils." While some may hesitate to subscribe wholly to this view, few, if any, will deny that it is the duty of the profession to sternly rebuke the government of the University for its action in this wretched business, and to display their disapprobation by warning students against a school whose diploma has been so depreciated that winning it cannot be esteemed a rational object of ambition, and which has a faculty "two-thirds of whose members," as that grand old scholar and gentleman, Dr. Sager, tersely puts it, "are silent partners in a homœopathic firm of teachers."

FREDERIC HENRY GERRISH.

PORTLAND, MAINE, August 25, 1875.

DR. ALEXANDER FLEMING, of Birmingham, England, died at Buxton, on the 21st of August, aged fifty-two, of chronic renal disease. To the profession of this country he is best known by his researches on the action of aconite. Until 1873, when ill health obliged him to relinquish active work, he had for many years been Professor of Materia Medica at Queen's College, and held many honorable professional positions. He was very successful as a clinical teacher, and his knowledge of therapeutics was very comprehensive. Personally he was as much distinguished for the gentleness of his character as for the thoroughness of his work.

LIST OF THE SUBJECTS TAUGHT AND OF THE TEACHERS IN THE RESPECTIVE SCHOOLS INCLUDED IN THE FOLLOWING TABLE.

SUBJECTS TAUGHT.	MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA, PHILAD.	JEFFERSON MEDICAL COLLEGE, PHILAD.	MEDICAL DEPARTMENT OF HARVARD UNIVERSITY, BOSTON.	BELLEVUE HOSPITAL MEDICAL COLLEGE, N. Y.	WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY, N. Y.	MED. DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.	COLLEGE OF PHYSICIANS AND SURGEONS, MED. The regular winter courses in the foregoing schools commence as follows:—

Tuesday, Sept. 7.—Albany Med. College.

Wednesday, Sept. 29.—Bellevue Hospital Med. College, and the Med. Dept. of the Univ. of the City of New York.

Thursday, Sept. 30.—Med. Department of Harvard Univ.

Friday, Oct. 1.—College of Physicians and Surgeons.

Monday, Oct. 4.—Med. Department of the University of Pennsylvania, and Jefferson Med. College.

Tuesday, Oct. 5.—Woman's Medical College of the N. Y. Infirmary.

CHANGES IN THE PUBLIC SERVICE.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Sept. 5th, 1875, to Sept. 11th, 1875.

ARMY.

WEEDS, J. F., Surgeon.—Granted leave of absence for one month on surgeon's certificate of disability. S. O. 128, Dep't of the South, Sept. 8, 1875.

HUNTINGTON, D. L., Assistant Surgeon.—When relieved by Assistant Surgeon Price, to comply with par. 5, S. O. 158, c. s., A. G. O. S. O. 93, Dep't of California, August 25, 1875.

O'RIELLY, R. M., Assistant Surgeon.—Relieved from temporary duty at Fort Hamilton, N. Y. H., and to rejoin his station, Fort McHenry, Md. S. O. 175, Mil. Div. of the Atlantic, Sept. 3, 1875.

KIMBALL, J. P., Assistant Surgeon.—Leave of absence extended one month. S. O. 97, Mil. Div. of the Missouri, Sept. 8, 1875.

PRICE, C. E., Assistant Surgeon.—Assigned to duty at Angel Island, Cal. S. O. 93, c. s., Dep't of California.

NAVY.

September 8.

SCOFIELD, W. K., Surgeon.—Ordered to the receiving ship *Ohio*, at Boston.

WOOLVERTON, T., Surgeon.—Detached from the receiving ship *Ohio*, at Boston, and ordered to the Naval Hospital at Norfolk, Va.

COOK, GEORGE H., Surgeon.—Detached from the Naval Hospital at Norfolk, Va., and placed on waiting orders.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

[THE MEDICAL RECORD is published every Saturday. Notices of meetings, lectures, operations, etc., intended for publication in this bulletin should be received at the office, 27 Great Jones Street, one week previous, to insure their appearance.]

Monday, Sept. 20th.—Sect. of Obstetrics of the N. Y. Acad. of Med., 12 W. 31st street.—N. Y. Soc. of Neurology and Electrology.

Tuesday, Sept. 21st.—N. Y. Obstetrical Soc.—Med. Soc. of the Co. of Kings.—Semi-Annual Meeting of the Homeopathic Medical Soc. of the State of N. Y., at the Ophthalmic Hospital, cor. Third av. and 23d st.

Wednesday, Sept. 22d.—N. Y. Pathological Soc.—Homeopathic Med. Soc. of the State of N. Y.

Thursday, Sept. 23d.—N. Y. Medico-Legal Soc. "The Penal Laws Relating to Suicide in Ancient and Modern Times," by R. S. Guernsey, of the N. Y. Bar.

Monday, Sept. 27th.—Med. Soc. of the Co. of N. Y., Nomination of officers.

Tuesday, Sept. 28th.—Adjourned Annual Meeting of the Alumni Association of Bellevue Hosp. Med. Col., at the rooms of the Academy of Medicine, 12 West 31st st., at 8 P. M.

Friday, Oct. 1st.—Medical Library and Journal Assoc. (first meeting of the season).

THE UNIVERSITY OF ODESSA, in Russia, is taking measures to establish a Department of Medicine.

DR. SMITH-SHAND has been appointed to the Chair of Practice of Medicine in the Scottish University of Aberdeen.

DR. JOHN H. POOLEY, of Yonkers, has accepted the position of Professor of Surgery in Starling Medical College, Columbus, Ohio.

American Pharmaceutical Association.

TWENTY-THIRD ANNUAL MEETING OF THE AMERICAN PHARMACEUTICAL ASSOCIATION.

[Special report for THE MEDICAL RECORD.]

THIS Association met at Boston, September 7th, for the fourth time in its history. Its objects are the general improvement of the science and art of pharmacy, the elevation of the standard of education, etc., and the Association numbers about 1,000 active members.

ANNUAL ADDRESS.

A committee on credentials being appointed, Mr. C. Lewis Diehl, of Louisville, Ky., read his annual address, which alluded to the contributions to science which pharmacists were constantly making, and to the improved methods of obtaining results through the rapid strides of modern chemistry. Methods of preparation of remedies have thus been developed which make their production on a large scale remunerative. Hence the pharmacist depends on commerce for many of the products that were formerly prepared by him, and as a consequence can confine his attention mainly to the determination of the purity of his purchases and to the production of galenicals. He then alluded to several recent remedies, restricting himself rather to their general features than their therapeutic relations, such as salicylic acid, jaborandi, and digitaline, and other substances obtained from digitalis. As most of the processes of obtaining these remedies are detailed in the medical and pharmaceutical journals, we need not detail them here. Salicylic acid differing from carbolic acid by having two additional equivalents of carbonic acid, the carbolate of sodium is heated in a perfectly dry and dusty state to a certain temperature, and carbonic acid passed through the mixture, a large proportion of the carbolic acid being thus converted into the salicylic acid. By proper methods it is then readily purified, and found to be identical with the salicylic acid obtained from wintergreen.

The President also recommended changes in the constitution and a different method of disposing of papers, so that objectionable ones might be returned to the author, and modifications made by him, if necessary.

OFFICERS OF THE ASSOCIATION.

The officers of the Association for 1875 are the following:—*President*, C. Lewis Diehl, of Kentucky; *Vice-Presidents*, Joseph Roberts, of Maryland, Wm. T. Wenzell, of California, Augustus R. Bayley, of Mass.; *Treasurer*, Charles A. Tufts, of N. H.; *Permanent Secretary*, John M. Maisch, of Penn.; *Local Secretary*, S. A. D. Sheppard, of Mass.; *Reporter on Progress of Pharmacy*, C. Lewis Diehl, of Ky. The Committee on Credentials reported the names of more than a hundred candidates for membership, all of whom were elected.

The constitution prescribes that "every pharmacist and druggist of good moral and professional standing, whether in business on his own account, retired from business, or employed by another, and those teachers of pharmacy, chemistry, and botany who may be especially interested in pharmacy and materia medica, who, after duly considering the objects of the Association and the obligations of its constitution and

by-laws, are willing to subscribe to them, are eligible to membership."

Objection was made to one of the candidates, Prof. S. P. Sharples, State Assayer, and Prof. of Chemistry in the Boston Dental College, as being ineligible from his non-connection with a college of pharmacy, but the chair deciding in his favor he was elected. A Committee on Nominations was then appointed, and other Special Committees, after which the Association adjourned.

OFFICERS ELECT.

On Wednesday morning the session opened with the report of the Committee on Nominations as follows:

President—Professor George F. H. Markoe, of Boston.

Vice-Presidents—Fred Hofiman, of New York, T. Roberts Baker, of Richmond, C. F. G. Meyer, of St. Louis.

Treasurer—Charles A. Tufts, of Dover, N. H.

Permanent Secretary—Professor John M. Maisch, of Philadelphia.

Reporter on Progress of Pharmacy—C. Lewis Diehl, of Louisville, Ky.

Executive Committee—George W. Kennedy, Pottsville, Pa.; Joseph L. Lemberger, Lebanon, Pa.; William M. McIntyre, Philadelphia; Charles A. Heinitsh, Lancaster, Pa.; John M. Maisch, Permanent Secretary, *ex-officio*.

Committee on Papers and Queries—William Saunders, Ontario, Can.; Emil Shaffer, Louisville, Ky.; James H. Taylor, New York.

Business Committee—Jacob D. Wells, Cincinnati; Paul Balluff, New York City; William C. Bakes, Philadelphia.

These gentlemen were elected, and the new President at once entered upon his duties.

The report of the Executive Committee was read by the chairman, George W. Kennedy. Since the organization of the Society there had been a total membership of 1,697; died, 136; dropped for various causes, 477; resigned, 101; leaving a balance of 983. The number of honorary members was 30, of whom 10 had died. The report closed with obituary notices of the members who had died during the year.

REPORT OF SECRETARY.

The report of the Permanent Secretary was then read by that officer, Prof. John M. Maisch, of Philadelphia. After discussing matters connected with the next annual meeting, he stated that the invitation of the Association to the Fifth International Congress, to meet in Philadelphia during the Centennial year, was laid before that body at its meeting in St. Petersburg, but no decision had been arrived at, the selection of the time and place of meeting being in the hands of the executive committee of that organization. The Congress expressed itself by resolution in favor of meeting in London, and several speakers advocated an interval of five years before another meeting. After the adjournment of the International Congress the members met and divided among themselves a draft of an international pharmacopœia prepared by the Paris Pharmaceutical Society, and agreed upon the principles which should guide the review and completion of the draft. It was decided that evaporation *in vacuo* should not be directed in the preparation of extracts; that the fluid extracts of the United States Pharmacopœia should be critically examined; and that the temperature for taking the specific gravity of all liquids should be uniformly 59° Fahrenheit. It was expected that the critical review of the submitted

draft would be completed by December, when it was to be multiplied and communicated to the various pharmaceutical societies for examination and report. At the meeting in Louisville the Association decided to participate in this undertaking, and correspondence to that end was now in progress. A cordial invitation had been extended to the pharmacists of all nations to meet with the American Pharmaceutical Association in 1876. The secretary recommended that the Association communicate directly with the various national and local societies of foreign countries upon this subject. The Philadelphia College of Pharmacy had invited the members of foreign societies to make the college building their headquarters, and proposed to engage proper persons to give needful and useful information to strangers. As the chief interest outside of the sessions of the Association next year would centre in the Centennial Exposition, where pharmaceutical and allied products from all parts of the world would be exhibited, the report recommended that no exhibition be held by the Society at its next meeting. The secretary had read a paper on American Pharmacy and its Relations to Public Health, before the American Public Health Association, in Philadelphia, in November, 1874, and had discussed therein the importance of pharmacy to the public welfare and health, the large amount of spurious and adulterated drugs and preparations formerly imported into this country, and the salutary effect of the drug law; also home adulterations, patent medicines, and measures to decrease their sale, and other questions of importance to the pharmacist and the public; urging particularly the necessity of the enactment of laws regulating and restricting the sale of drugs and medicines to properly educated pharmacists.

UNOFFICIAL FORMULÆ.

The Committee on Unofficial Formulas presented their report through their chairman, R. V. Mattison, of Philadelphia. The province of this committee is to collect such formulas as are found to be in use in the preparation of extracts, elixirs, etc., which have not become official by being admitted to the United States Pharmacopœia. The report covered twenty-two such formulas. It appearing that the formulas for elixirs would again be represented in the report of the Committee on Elixirs—on the principle that a double-barrelled gun is twice as effective as a single-barrelled gun, it being desirable to sweep away the whole elixir business—the report of the committee was amended by striking out the elixir formulas, and then accepted; the formulas thus stricken out were referred to the Committee on Elixirs.

The Treasurer reported a balance of \$873.16, and the Executive Committee suggested the names of 122 candidates for membership, all of whom were elected.

REPORT OF COMMITTEE ON ADULTERATION.

DR. A. W. MILLER, of Philadelphia, then read the report of the Committee on Adulteration and Sophistications. To give the subject the widest publicity advertisements were inserted in the pharmaceutical journals requesting information of adulterations and sophistications of drugs, chemicals, and kindred articles. Some of the important adulterations had been brought to the notice of the pharmaceutical meetings of the Philadelphia College of Pharmacy, and in several instances their fraudulent character exposed and their further sale materially affected. The report called especial attention to frauds in the sale of essential oils, although it was not always possible to prove the admixture by positive chemical tests. A New

Jersey distiller had frankly admitted that all the commercial oils of cedar, hemlock, and spruce made by him and his acquaintances were prepared by putting the branches of the respective trees into the still, with an amount of turpentine proportioned to the price they expected to realize; and prided himself not a little on the superiority of these *distilled* oils over those made by mere admixture with turpentine. The major portion of the more expensive oils are consumed by bakers, confectioners, soap-makers, and bottlers of mineral or soda water, who have no means for testing them, and thus become easy victims to such swindles. The writer had on two occasions purchased cans of oil of lemon, one of which contained but 75 per cent. of oil, and the others scarcely 33 per cent. These adulterations were also becoming common in Europe. A gentleman who claimed to have formerly held responsible positions in two of the largest German houses, had shown him a full line of receipts for mixing and cheapening all the more prominent oils, which he was anxious to compound in this country. Some of the adulterations which are of public interest were musk, a caddy of which, weighing 19½ ounces, was proved in an English court to contain only 6½ ounces. French oil of almonds, stated on undoubted authority to be obtained exclusively from peach kernels; honey, made by melting cane or other sugar in a decoction of slippery-elm bark or a solution of gum and starch; linseed oil, adulterated with hemp, fish, rosin, and mineral oils; beeswax, consisting almost entirely of black earthy matter neatly coated with handsome yellow wax by repeatedly dipping it into the melted wax, and also adulterated with paraffine; castor-oil, composed of lard and ereton oils, etc.

LEGISLATION AND THE CONSTITUTIONALITY OF THE PHARMACY LAWS.

On Wednesday afternoon, after extending an invitation to the medical men of Boston to attend the sessions, the Association listened to the report of Prof. John M. Maisch, on Legislation, the constitutionality of the pharmacy laws being chiefly discussed.

A question had been raised whether these were unconstitutional, but they had been sustained in the lower courts. The laws had been generally carried out satisfactorily, this being shown by the rejections, amounting frequently to more than twenty-five per cent. of those examined. In a portion of Canada a law was proposed, but withdrawn on account of the opposition of the medical profession. The pharmacutists of the United States had been much annoyed by the stamp tax imposed under the revenue law, but a section of the "little tariff bill" had removed the difficulty. This stipulated that no tax should be imposed on any medicinal articles prepared by any manufacturing chemist, pharmacist, or druggist, in accordance with a formula published in any standard dispensatory or pharmacopœia in common use by physicians and apothecaries, or in any pharmaceutical journal issued by any incorporated college of pharmacy, when such formula and where found shall be distinctly referred to on the printed label attached to such article, and no proprietary interest is claimed therein; and that no stamp should be required when the formula of any medicinal preparation was printed on the label attached to such article and no proprietorship was claimed. These requirements, although a departure from the custom hitherto followed, would entail no hardship upon the pharmacist and druggist, and would enable him to keep on hand ready for delivery any legitimate medicine, without being ranked with the manufacturer of patent medicines.

THE EBERT PRIZE.

The Ebert Prize was awarded by the committee to Charles L. Mitchell, of Philadelphia, for an essay on "The Active Principles of the Official Veratrum."

REPORT OF THE COMMITTEE ON ELIXIRS.

The report of the Committee on Elixirs was then read by Wm. McIntyre, of Philadelphia. They were of opinion that such a nomenclature should be adhered to as would best express the remedial composition. A uniform simple elixir that would answer general purposes would meet all ordinary requirements, and serve as a guide to the physician. The tendency of the pharmacopœia was to present simple preparations, more thoroughly representing the drugs from which they were prepared. More attention was demanded, therefore, in the construction of extemporaneous formulas, and a thorough knowledge of the various spirits, syrups, and aromatic waters would give a wide field for the choice of auxiliaries, correctives, and vehicles. The report also presented a revised list of formulas. In the discussion that followed it was contended that some of these were defective; that some of those proposed last year were unsatisfactory; that the sense of the Association was adverse to elixirs, etc., and Mr. Baker, of Virginia, stated that formulas might be adopted but would be of little use unless physicians ordered them. For the purpose of interesting the medical profession in the matter, the Washington College of Pharmacy and the Medical Association of that city had co-operated. The formulas as reported were adopted.

Dr. A. W. MILLER, of Philadelphia, then read the report of the Committee on Publication of Papers. A question having arisen whether authors should be allowed to publish their papers in medical or pharmaceutical journals in advance of their publication in the Association volume, it was

Resolved, That the various pharmaceutical and medical journals are cordially invited to publish whatever notes they may desire to make of our proceedings and of the scientific papers which are read before our meetings.

Resolved, That when authors of scientific papers have prepared copies or abstracts of their essays previous to the meeting of the Association, they shall be at liberty to distribute such copies or abstracts at any time subsequent to the official reading of their respective papers, provided that the paper is always headed in publication by the statement that it has been read at our meeting.

READY-MADE PILLS.

A report was made by Mr. Balluff, of New York, on "The Progress of Subscriptions to the Liebig Monument," after which Prof. Joseph K. Remington, of Philadelphia, offered, through Mr. Sanders, of Ontario, a paper on "Ready-made Pills of our Day," in which he replied to the query, "Can the form of the pill, the character of the coating, or injury during the coating by heating, interfere with its solubility?" and showed that the uncoated pill was, of course, the most soluble, and next in order the sugar-coated, the compressed, and the gelatine-coated. An essay was also read by Mr. B. F. Stacy, of Massachusetts, on "Paraffin and its Uses, and especially as a Substitute for Wax;" Prof. Babcock, describing a compound, called also paraffin, of lard-oil, and wax and paraffin mixed, which was employed as a substitute for lard; and Mr. Lemberger, of Pennsylvania, referring to the use of paraffin oil for producing a permanent base for ointments.

LEGIBLE WRITING IN PRESCRIPTIONS.

Mr. T. R. BAKER, of Va., presented an extract from the minutes of the Richmond Pharmaceutical Association, Nov. 20, 1874, embracing resolutions to be presented to the Academy of Medicine of that city, urging the importance of writing prescriptions in a legible hand, without erasures or interlineations; of using the technical language and abbreviations of the Pharmacopœia and the United States Dispensatory; of writing directions for use and dose as a guide to the dispenser in case of error in quantity of any active ingredient; that when an unusual dose or quantity of a potent medicine is prescribed, the prescriber should affix a caution mark or sign to inform the dispenser the dose is unusual; that the words "not renewable" should be written on prescriptions which they did not desire to be renewed; also the importance of using every possible means to stop the sale of opium, morphia, and chloral, except upon competent medical authority. A similar communication was received from the delegation from the Philadelphia College of Pharmacy, and both papers were referred to a committee appointed by the chair.

On Thursday volunteer essays and answers to queries propounded at the previous annual meeting were presented. These consisted of an account of adulteration of granulated sugar with ground rice; an account of the various forms of drug-mills; an essay on mezquite gum for pharmaceutical purposes, and even as a substitute for gum arabic in its medicinal uses; and some important papers on phosphorus and its compounds, and the methods of administering them. Mr. Lewis Dohme, of Maryland, found by careful analysis that the commercial glacial phosphoric acid was contaminated with over fourteen per cent. of soda, the presence of which prevented the conversion of metaphosphoric and pyrophosphoric acid into tribasic acid.

NEW METHOD OF MAKING PHOSPHORIC ACID.

Prof. MARKOE presented a new method of making phosphoric acid from phosphorus, nitric acid, water, bromine or hydrobromic acid, and a small quantity of iodine. A paper with conclusions similar to those of Mr. Dohme was offered by Prof. Jos. P. Remington, of Philadelphia. Prof. Markoe also read a paper on the manufacture of hydrobromic acid by the union of phosphorus and bromine in the presence of ice or ice-water. An essay on chloral-hydrate was read by T. Roberts Baker, Richmond. The writer stated it possessed powerful antiseptic properties, and numerous experiments showed it could be used to preserve anatomical preparations much better than any of the liquids heretofore used for that purpose.

MAXIMUM DOSES.

The report of the Committee on Maximum Doses was presented by the chairman, Dr. Wilson H. Pile, of Philadelphia. In view of the wide difference of views in regard to the quantities of potent remedies which could safely be administered, they had come to the conclusion that an arbitrary list of maximum doses made from such conflicting authorities would be of no practical utility. They therefore suggested that a committee be appointed to confer with the American Medical Association on the subject, as well as the proper signs to be adopted to designate the correctness of larger doses when intended by the physician. The recommendation was adopted.

PROGRESS OF PHARMACY.

The report on the progress of pharmacy was presented by the reporter, C. Louis Diehl, of Louisville,

Ky. The report contained a more accurate and a fuller review of pharmaceutical and chemical literature than any previously made. The report was divided into five sections: First, pharmacy, under which head were comprised the various pharmaceutical papers. Second, *Materia medica*, which gave the results obtained during the year in the history of crude drugs and their botanical characters. Third, Inorganic chemistry, giving the results of investigations of inorganic substances. Fourth, Organic chemistry, giving the results of investigations upon the crude vegetable drugs during the year, with the progress in general organic chemistry. The report concluded with a review of the various works relating to these subjects during the year.

PAPERS ON VARIOUS SUBJECTS.

In the afternoon papers were read on the various forms of suppository moulds; on iron combinations, which were said to be only admixtures instead of definite saline compounds; on iodoform; spiritus ammoniæ aromaticus; chlorodyne, a new formula of which was suggested to be called officinally liquor chloroformi compositus; on artanthe elongata; on insect injuries to rhubarb; on pancreatine, which was said by Prof. Scheffer, of Louisville, to become destroyed on its entrance into the stomach, and therefore of no therapeutic value; on the danger of explosion from mixing nitric and carbolic acids; on the best tests for purity of chloral hydrate, the writer stating that hydrate of sodium yielded a better result than hydrate of calcium for separating the chloroform, and that formic acid was the most injurious contamination likely to be found; an excellent essay on the preparation of the bromides of the organic and inorganic bases used in American pharmacy, by Mr. Charles Bullock, of Philadelphia; a paper on scammony resin; on the various pharmaceutical preparations of calabar bean; on the alkaloids of cinchona; on the determination of the quinia strength in citrate of iron and quinia; and on the solubility of sulphate of morphia.

PATENT MEDICINES.

PROF. MAISCH spoke of the immense traffic in patent medicines. The Association professed to be opposed to the sale of these medicines. The efforts of pharmacists in this direction would amount to nothing so long as patent medicines were called for by the public. The question had been agitated what was the best means of informing the public of the dangerous nature of many of these nostrums. Dr. Frederick Hoffman, of New York, had suggested the publication of a health almanac, similar to those issued by the proprietors of patent medicines, which should contain analyses of such preparations. Circulars had been prepared upon this subject, which Mr. M. desired to have distributed to the Association.

On Friday morning, on motion of Prof. Sharples, of Boston, a committee of three was appointed to consider the subject of metric weights and measures. He stated that a similar resolution had been passed by most of the scientific bodies in the country. No profession was more deeply interested in the subject than the pharmaceutical, which had to deal with two varying systems of measures, mixing by one and selling by the other. The process of converting one measure into the other was very difficult, and not generally understood. All the trouble arising from this source would be obviated by the adoption of the metric system.

IMPURITIES IN SULPHURIC ACID.

Papers were presented on impurities in sulphuric ether and bicarbonate of sodium, by Prof. Bedford of

New York, the analysis of the latter giving the amount of carbonic acid, dried carbonate of sodium, and chlorides and sulphates present, although but a small amount of impurity was detected; on a new method of packing herbs; on cod-liver oil; on a new mode of administering medicines, between two layers of flour-paste disk; on a new process for making iodide of arsenic; on *grindelia robusta*; on spiritus ammoniæ; on dilute hydrocyanic acid; on the production of "rubber" from the common milk-weed, *asclepias cornuti*, etc., etc. We regret that space forbids us from making more than a passing allusion to some of these valuable papers.

Previous to the passage of resolutions of thanks to the Bostonians and the adjournment, which was to the second Tuesday of September, 1876, at Philadelphia, the interests of the Association was centred in a very important question of professional decorum, being no less than a charge of suspected illicit diploma selling.

On Thursday evening a conference of members of teaching colleges of pharmacy was held, at which the following action was taken:

"Resolved, That this conference communicate to the American Pharmaceutical Association that they are in possession of documentary evidence that the Tennessee College of Pharmacy was opened through its treasurer and acting secretary to examine candidates and graduate them, without their attending the customary courses, just the same as if they had attended all the lectures.

CHARLES A. TUFTS, President.

JOHN M. MAISCH, Sec. Conf. School of Phar."

On motion of Mr. Roberts, of Baltimore, the documentary evidence was produced and read. It consisted of a letter from Mr. B. S. Lillard, substantially the offer contained in the above.

PROF. BEDFORD, of New York, offered a resolution which was adopted, that a committee of three be appointed to communicate with the Tennessee College of Pharmacy and inquire whether such action was authorized by the college or was undertaken on the individual responsibility of Mr. Lillard.

MR. LILLARD seconded the motion and explained the action of the Tennessee College. The latter college conferred upon its graduates the degree of Doctor of Pharmacy. The other colleges conferred the degree of Graduate in Pharmacy. Persons who were already graduates of other colleges had applied to the Tennessee College for its degree, preferring the title of doctor to that of graduate. It was customary for colleges to recognize attendance upon courses of instruction in other colleges, and it was the intention of the Tennessee College, and the meaning of the letter which had been read, to signify a willingness to confer the degree of doctor upon graduates of other institutions without requiring attendance upon all the lectures. The degree would not be conferred without examination.

In connection with the meeting of the Association, a beautiful and costly display of pharmaceutical specimens, chemicals, druggists' sundries, etc., was made, which attracted very general attention.

A NEW FOUNTAIN IN ST. LOUIS.—The King Brothers, of St. Louis, have erected in that city, for the benefit of the public, a drinking-fountain, capable of supplying three thousand gallons of iced water daily. The fountain is of marble, and is provided with ten faucets, which are each supplied with nickel-plated drinking-cups. A contemporary remarks that this is better than sumptuary laws and crusading against drinking saloons.

Reports of Hospitals.

ROOSEVELT HOSPITAL.

NOTES OF PRACTICE AND ITEMS OF TREATMENT.

DR. HEINEMAN, HOUSE-PHYSICIAN.

CHOLERA MORBUS.

PATIENTS admitted with this disease have been uniformly treated by placing them in bed, and administering ipecac, opium, and cinnamon in small doses. The following is the prescription which has been commonly employed:

R. Ipecac.....	gr. $\frac{1}{2}$
Opium.....	gr. $\frac{1}{4}$
Cinnamon.....	gr. $\frac{1}{2}$
M.	

Such a dose is administered every four hours at first, and as the symptoms subside, once in eight. The ipecac, however, is gradually increased in quantity to one grain, one grain and a half, etc., until three-grain doses are reached. The intense thirst, which is quite common in this class of cases, is met with pellets of ice chiefly. Two patients were seen. One had passed about a pint of fresh blood early in the attack. Both were convalescing rapidly.

CROUPOUS PNEUMONIA—PHthisIS.

This case illustrated how well some patients suffering from phthisis will sustain an attack of pneumonia.

A female patient, *æt.* thirty-six, who had a small cavity in the apex of her right lung, was attacked with a pneumonia which involved the lower lobe of the left lung. The acute disease had ceased advancing. Her pulse had ranged from 108 to 118, and the temperature from 99° to $101\frac{1}{2}^{\circ}$ F. The treatment consisted in administering quinine, stimulants, and a liberal diet, and the patient was exceedingly comfortable.

CHRONIC DYSENTERY.

The dysenteric symptoms in this, and a number of other cases, had been effectually relieved by the use of thirty drops of the fluid extract of ergot three times a day.

Some cases of acute form of the disease, for instance, when the patient had had six or eight passages daily, had yielded promptly to the same plan of treatment. In both instances the patients were kept in bed.

GASTRIC ULCER.

A male patient was admitted who had unmistakable symptoms of this affection, and had been vomiting almost incessantly for more than a week. The only treatment he received was a tablespoonful of milk every hour. The vomiting at once began to subside, and with the subsidence the amount of milk was increased gradually to half a glass. The patient was feeling well again. The simplicity of the treatment was the noticeable feature.

DOUBLE PNEUMONIA.

There were some features in the following case which are perhaps worthy of note. A male patient, *æt.* thirty-four, and an habitual drunkard, had been on a spree a week or more, when he was seized with chills and was soon brought to the hospital. At the time of admission there were present evidences of general bronchitis and slight pneumonia. The bronchitis had gradually disappeared, and the pneumonia had continued to extend until it involved almost the entire left

lung and the lower lobe of the right. His respiration was forty to the minute when admitted, but had subsided to thirty.

The characteristic expectoration of pneumonia has not been present, which is frequently the case in the pneumonia of drunkards. The pulse and temperature were worthy of note, especially in connection with so large an amount of lung consolidation. Upon admission the pulse was 124, and now, at the fifth day since admission, it numbered 108. The temperature had ranged from $99\frac{1}{2}^{\circ}$ to $100\frac{1}{4}^{\circ}$ F., and at the fifth day stood at 100° F.

The patient, notwithstanding his habits, had had *wet cups* (3) applied over the sternum, with dry cups over the entire chest, posteriorly, and the abstraction of this small quantity of blood had been attended with good results. The treatment in other respects consisted in the use of six grains of the sulphate of quinine three times a day, an ounce of brandy every hour at first, and carbonate of ammonia. The patient looked very comfortable, and the indications were that he would recover, although the consolidation was quite extensive.

SURGICAL DIVISION.

[DR. WENDOVER, HOUSE-SURGEON.

FRACTURE OF BOTH PATELLE—DOUBLE FRACTURE OF RIGHT PATELLA.

The fractures occurred as the result of sudden and violent muscular contraction. The man had slipped and brought unusual strain upon the left leg; the patella gave way, and in his efforts to save himself from falling brought his right leg to the rescue; but the undue exertion produced a double fracture of the patella of that limb, and his efforts at maintaining the erect posture ceased. He was a man of good habits, and apparently healthy, but previous to this group of accidents had suffered from fracture of the leg three times. The simplicity of the dressing was worthy of note, especially when the result obtained entered into the estimate. For the fractured edges of the left had been held in almost perfect coaptation, and of those of the right the edges of the lower fracture were closely in contact, while of the upper they were not separated more than three lines. The fractures were all transverse. The dressing consisted of two tabs, one carrying a buckle, which were secured by means of adhesive plaster, one upon the thigh and the other upon the leg. The limb was then placed upon a straight posterior splint, after which the fractured edges were approximated, a small, firm roller placed above and below the patella, and then secured by means of the tabs first applied to the limb.

HEMORRHOIDS.

In this case the hemorrhoidal tumors had been removed according to Allingham's method, which consists in first cutting through the tissues at the base of the tumor down to the vessels, and then applying a ligature. The cure was complete.

SCROTAL HYDROCELE—RADICAL CURE.

The patient who was the subject of this affection had been treated by puncture and injections of iodine, but without effecting a permanent cure. The house-surgeon, therefore, made a free incision into the sac, broke up some of the adhesions with the finger, which had probably been produced by former treatment, and irritated the inner surface of the cavity quite smartly. Considerable inflammatory action followed, but this soon subsided and a radical cure was effected.

BURNS.

A male patient had been burned over the head and face with kerosene oil. The dressing employed in this case, a favorite with the visiting surgeon, consists of:

R Acid tannic. ʒ ij.
 Lotion plumbi cum opio. ℥ i.
 M.

This is applied by wetting strips of lint or muslin in the mixture and laying them upon the burned surface; and is regarded as a very nice dressing when there is a discharge. The burns in this case were not deep, the discharge had ceased, and the sores were being dressed with oxide of zinc ointment.

PERITONITIS—HYPODERMIC INJECTIONS.

As soon as symptoms of peritonitis were developed the administration of opium was commenced; but the respiration of the patient remained unaffected although the pain was overcome. No symptoms of narcotism manifested themselves; but, on the contrary, the patient was quickly aroused by the most trifling disturbance. Hypodermic injections of morphine were substituted for the aqueous extract of opium, the preparation that had been previously employed in the treatment of the case, and the effect was to reduce the respiration from thirty to sixteen to the minute within twelve hours. The hypodermics were discontinued, and the extract again employed, but the respiration increased in frequency until the injections were again resorted to. The patient recovered.

GONORRHOEA—PERINEAL ABSCESS—SYMPTOMS OF PYÆMIA.

The special interest in this case was found in the plan of treatment. The patient had an attack of gonorrhœa. In the progress of the case a swelling was noticed in the perineal region, which was opened, and a free discharge of pus obtained. Not long after the patient was seized with chills, his temperature arose, profuse sweating followed, and this train of symptoms was also accompanied by other evidences of grave constitutional disturbance. The treatment consisted in use of a pure tonic stimulant, and nourishing course; but more special stress was laid upon the use of *morphine* in such doses as to allay all irritation. The patient was kept under the gentle, steady, quieting influence of the drug. This plan was regarded by the visiting surgeon with much greater favor than depending upon *quinine*, as is not infrequently done to a very great extent. The patient recovered.

CHOLERA IN SYRIA AND TURKEY.—*The British Medical Journal*, of August 21st, says that by the latest advices received from Syria, it appears that the number of cases of cholera in Damascus and Antioch are on the decrease. At Damascus, from the 20th to the 26th of July, there were six hundred and eighty cases, and five hundred and thirty-one deaths; and at Antioch, from the 19th to the 26th, there were one hundred and eighty-six cases, and one hundred and fourteen deaths. The cholera, it is stated, of the sporadic form, has appeared at Aleppo, where, from the 19th to the 26th of July, thirty-nine cases occurred, with twenty deaths. A correspondent in Constantinople writes that the Christian population of the city are becoming greatly alarmed. For some time past the necessity for sanitary reforms have been urged upon the municipal authorities, but they are utterly apathetic, and the city remains in just the same state that it was ten years ago, when the disease invaded the city and swept off the inhabitants at the rate of two thousand a day.

Progress of Medical Science.

SCHROEDER ON DRAINAGE OF DOUGLAS'S CUL-DE-SAC IN OVARIOTOMY.—At the session of the Physico-Medical Society of Erlangen, held May 10, 1875, Professor Schroeder made some statements on what he declared to be one of the most important questions in operative gynecology, viz., the drainage of Douglas's cul-de-sac in ovariotomy.* He said that after Peaslee had first recommended draining off the exudation from the abdominal cavity as the most efficient method of treatment in cases of peritonitis, Sims seized this idea, and came to the conclusion that Douglas's cul-de-sac had best be punctured and kept open in every ovariotomy, certainly in all in which a peritoneal exudation was to be expected on account of already existing peritoneal irritation or of extensive adhesions. The train of thought which Sims followed was, he said, essentially as follows: He assumes, and bases his assumption upon a series of fatal cases taken from Spencer Wells's operations, that the great majority of those dying after ovariotomy succumb to septicæmia, and that this is caused by an exudation which accumulates in the abdominal cavity, and undergoes decomposition into an ichorous fluid. Thus he arrives at the conclusion that the chief aim of a rational system of treatment must be to remove this exudation from the abdominal cavity, but that this can only be done easily and simply when the necessary precautions are taken during the operation. Very many in Germany have assented to these deductions, which Sims has advanced with the persuasive mastery of statement which is peculiar to him. Nussbaum especially adopts this idea with enthusiasm, and anticipates from it a new curative measure in ovariotomy, and Spiegelberg is also warmly in favor of it. I see, he says, in these views an essential danger for ovariotomy, and cannot recognize the correctness of Sims's deduction. For agreeing as I do with Sims, that most of those operated on succumb to septicæmia, I still cannot concede that the reddish serous exudation plays the dreadful part that Sims ascribes to it; for daily experience teaches us that transudations and exudations in the abdominal cavity have in themselves no tendency to decomposition and the production of septic states. In fact, I have frequently satisfied myself that, even after ovariotomies, the exudation is not the bugbear that Sims considers it. I have three times operated under circumstances where an exudation into the abdominal cavity might certainly be expected, without the occurrence of the least trace of a septic process. In the first case I operated where an exudative peritonitis already existed. After the operation the meteorism and vomiting persisted for a few days, but soon improved, and recovery ensued without any disturbance. In the other two cases, to be sure, death occurred, but only after twelve and fifteen days respectively, and from a complication, viz., tetanus, which was not in any degree dependent upon septic processes in the abdominal cavity. In the first of these cases the whole anterior surface of the tumor had contracted adhesions to the abdominal wall, so that the recognition of the peritoneum and the separation of the tumor from it presented great difficulties. From the extensive surfaces

* This note was intended for the article on Ovariotomy in the American Edition of Ziemssen's *Cyclopædia of the Practice of Medicine*, vol. x. It did not, however, reach New York in season to be printed in that volume.

of cicatricial adhesion an exudation would necessarily take place. In spite of this, there was perfect healing of the abdominal wound; there was no trace of peritoneal irritation, and when death, occurring on the ninth day, furnished the opportunity for an autopsy, the abdominal cavity was found perfectly healthy, and there was no suspicion of a decomposing exudation. In the last case the adhesions were not so extensive as they were firm, and could only be separated with great difficulty. Here there existed a reddish, serous transudation in the abdominal cavity, which constantly reaccumulated even during the operation, and a part of which had to be left in the abdominal cavity. The patient had hardly the least sensitiveness, very little fever, and was perfectly well after eight days. She had a normal temperature and a strong appetite, in fact showed no septic phenomena at all. Death also ensuing from tetanus as before, but on the fifteenth day. Small fibrinous flocculi were, it is true, found in the abdominal cavity upon the intestines, also in a few places small deposits of pus, which could easily be scraped off with the blade of the knife, and in the true pelvis there was a reddish, serous fluid. Notwithstanding, there were no septic phenomena, and she would undoubtedly have recovered had the calamitous tetanus not appeared as an intercurrent disease. Now, how does it happen that in one case an exudation undoubtedly present occasions no disturbances whatever, does not even perhaps furnish slight symptoms of peritonitis, while at another time, with a very slight operation, involving scarcely any injury of the peritoneum, there are associated the most violent symptoms of septic peritonitis? According to my conviction, this difference depends wholly upon whether infection has or has not taken place. In its absence the exudation is perfectly harmless, and is easily absorbed by the peritoneum without irritation; should it occur, however, the exudation becomes decomposed, or where there was no exudation, a violent peritonitis sets in, which furnishes a rapidly decomposing exudation. If this view be correct, it is evident that our treatment must be directed not to the accumulating secretion, but to the prevention of the infection from which the whole trouble arises. Now, although in spite of all our experiments on vibriones, we still do not know precisely in what the infective substance consists, I am, nevertheless, certain that it is conveyed from without, and that its conveyance is as a rule by the hands, the instruments, or other appliances of the operator and his assistants. If, therefore, we wish to ward off the infective substances, we must operate in healthy places, and must attend most carefully to the absolute cleanliness of our hands, linen, clothing, instruments, sponges, etc.; also, in order to disinfect as far as possible the air which forces its way into the abdomen, it is desirable to operate under the spray of carbolic acid, as is my custom in every case. If with such painstaking exactitude we guard against infection, the exudations do not decompose, and consequently give rise to no septic phenomena. Under these circumstances, then, drainage is unnecessary, and if unnecessary, ought to be omitted, as in any event it makes the operation more complicated, difficult, longer, and more dangerous. I should therefore decide upon drainage during the operation only in case I believed—a state of things which of course should not happen—that the patient had become infected, or in case decomposing masses, from some suppurating cyst, *e.g.*, had found their way into the abdominal cavity. Drainage of the abdominal cavity assumes a very different position as a therapeutic measure against a septic peritonitis which already exists. For, although the exudation be neither the original cause nor the

only symptom of the septic condition, it must still be conceded that its removal is highly desirable. It is true this is then difficult to accomplish. Douglas's cul-de-sac is easy to puncture only when an exudation is enclosed in it. Then only does a tumor form behind the uterus, which is easy to get at. It is precisely in these cases, however, that its evacuation is not absolutely demanded, for the exudation being encapsulated is rendered harmless, and does not lead to absorption or perforation. If, however, there is a free exudation in the abdominal cavity, it does not bulge forward in Douglas's cul-de-sac. It is then difficult and dangerous to puncture for fear of injuring the neighboring parts. The need of it is felt with especial frequency in puerperal peritonitis. But here the neck of the inverted uterus lies so close to the rectum that we do not know where to make the puncture. In such cases we might think of removing the exudation by incision of the abdominal walls. The abdominal cavity, however, cannot be satisfactorily washed out through a simple incision in the abdominal walls. So the only efficient procedure seems to me, in such cases, is to perform laparotomy, and then to perforate and establish drainage through Douglas's cul-de-sac from within. Perhaps this will yet become the treatment for septic peritonitis, although it requires great confidence to undertake this operation in a woman suffering from general peritonitis. In conclusion, let me once more state my views precisely, that the exudation after ovariectomy is not in itself the cause of the septicæmia, but is, on the contrary, perfectly harmless, unless it decomposes; but that decomposition only occurs after infection, and that consequently the important point is not the removal of the exudation, but the avoidance of infection.

THE SUBCUTANEOUS INJECTION OF CARBOLIC ACID AS AN ANÆSTHETIC AND ANTI-NEURALGIC.—Attracted by the published views of Prof. Hueter, Dr. Hermann Schulz began the use of carbolic acid as a subcutaneous injection, aiming at an antiphlogistic and anæsthetic effect. He has now used it in some forty cases. He uses a two-per-cent. solution of the purest carbolic acid in distilled water, and injects with a Pravaz syringe, which is filled quite full and is to be used from half full to twice full at one time, and repeated after some six or eight hours, if necessary, without regard to the presence or absence of fever. Out of over two hundred injections he has seen an abscess form but once, when the tissues had been lacerated by the sudden movement of a child's head during the little operation. He has had no experience in the use of parenchymatous injections. The results which he reports of his experience with the subcutaneous injections are by no means uniform. He has used them in cases of chronic inflammation, caries, and eczema, and found them inefficient; in some acute cases he had more favorable results, as in enlargements of the glands of the neck accompanying scarlatina and diphtheria; in a phlegmonous inflammation following dacryocystitis; in otitis externa and myringitis, and in one case of catarrhal conjunctivitis, though they failed in a second similar case. His use of this treatment in pneumonia does not wholly confirm the favorable opinion of Hagen. It had no marked influence upon the general course of the disease, but did effect a very prompt and marked relief of the pleuritic pain, and also of the cough, even when cups and sinapisms had proved ineffectual. The injections had to be repeated sometimes at the end of from four to eight hours. He regards this as a very important adjunct in the treatment of pneumonia. From his experience in the treat-

ment of some seven contusions, of intercostal neuralgia, periostitis of the jaw, hemicrania, and supraorbital neuralgia by these injections, he found that they generally produced early, and often permanent and complete relief of the pain, sometimes stopping the accompanying inflammatory process. Thus he believes that as an anæsthetic and anti-neuralgic remedy these injections may very often be advantageously substituted for narcotics.—*Allg. Med. Cent. Zeit.*, July 31 and Aug. 4, 1875.

HYSTERICAL SEIZURE IN A MAN TREATED AND CURED BY COMPRESSION OF THE TESTICLES.—The following case, reported by Dr. Foet, has an interesting analogy to the method of treatment of hysterical seizures in the female practised by Charcot, viz., compression of the ovaries. (*Vide* MEDICAL RECORD, June 19, 1875). A man was found apparently in an apoplexy. The mouth was half open, without frothing, the eyelids half closed, the head turned to the left. The respiration was slightly blowing, somewhat quickened, the belly distended, the pulse small. The patient, who was unconscious, occasionally made a movement with his hand to his neck, as if something choked him. The skin was insensible; but while they were attempting to examine the play of the pupils the face suddenly became distorted, the neck swollen, he ground his teeth, and his arms and legs became violently convulsed. Foet now pressed the testicles together, and in less than a minute the seizure had passed. The patient's mind remained confused for about an hour; then he stated that he sometimes suffered from a boring pain in the left temple, and that shortly before he became unconscious he had been attacked with a fit of incessant gaping. The velum palati and uvula were completely anæsthetic. The next day the patient was again at work. Dr. Geissler asks, pertinently enough, what led the reporter to think of the peculiar manipulation which was followed by relief? Was the cessation of the seizure merely accidentally simultaneous with the pressure on the testicles?—*Gaz. Hebd.*, 2 sér. 50, 1874.—*Schmidt's Jahrb.*, July 15, 1875.

TUBERCULOSIS TREATED BY INHALATIONS OF NITROGEN.—Dr. Steinbrück sets forth the following as the results of his experience in the treatment of chronic tuberculosis of the lungs by inhalations of nitrogen gas. In the first stage the disease is cured with positive certainty by systematic inhalations, if the cure is used long enough. He does not know whether relapses occur. In the second stage improvement and cures are attained to an extent hitherto impossible. The younger the patient the better is the withdrawal of oxygen borne, and the more certain is the result. In the third stage the inhalations are dangerous. All beneficial treatment of tuberculosis must depend upon quieting of the nervous system. The inhalations are practised in an air-tight cabinet, under the supervision of the physician, and the effects looked for are easier and deeper breathing, with coughing up at first of muco-purulent matter. Subsequently the cough should stop, the pulse and temperature fall, and the nervous system be calmed. Under these circumstances a cure is expected to follow. If these signs of improvement do not show themselves, Steinbrück regards it as useless to continue these inhalations, and resorts to stronger ones. With a larger proportion of nitrogen in the cabinet the patient, after a period of great restlessness, suddenly falls in a faint. He is then put to bed, and after a long sleep sometimes awakes with a great amelioration of symptoms, and sometimes the improvement only shows itself later. These are followed by increase of appetite, improved digestion,

and gain in weight after a few weeks. The details of a number of cases are added.—*Allg. Med. Cent. Zeit.*, Aug. 7, 1875.

TWO CASES OF RAPID MALIGNANT SYPHILIS.—Dr. E. Guibout reports that he has seen two cases in which syphilitic rupia was accompanied by continuous fever, great weakness, prostration, serious functional disturbances, and extensive ulceration—all within six weeks of the primary lesion. Moreover, none of the ordinary lighter syphilides had intervened. In the first case, that of a miserable anæmic woman, the rapid and unfavorable course of the disease was easily referred to her bad condition and circumstances, the chancres receiving no treatment until some three weeks after infection, and having become phagedænic at the end of two weeks. The second case, however, was that of a strong and healthy man, whose chancres received early and appropriate treatment, and the reporter could furnish no satisfactory explanation of its bad progress. The excessive discharge of ill-conditioned pus, the pain and irritation from friction and movement, these, with loss of sleep and the offensive smell, aggravated the bad features of the cases. At the end of two months, however, under tonic treatment and careful attention to cleanliness, supplemented by specific remedies, the first case was doing well, and the second was cured.—*L'Union*, 61, 62, 1875.—*Schmidt's Jahrb.*, July 15, 1875.

A DANGER FROM THE USE OF CHICORY IN COFFEE.—M. J. Clouët, Professor of Toxicology in the School of Medicine at Rouen, reports the following case: A family, consisting of five persons, were one morning, after having partaken of a light repast of coffee and milk, suddenly attacked with lassitude, headache, a sense of constriction in the throat, and all the food taken during the day had a disagreeable taste. These symptoms increased for several days, and the nights were troubled with unpleasant dreams. Still, nothing wrong in the diet was suspected, although one member of the family, who was in the habit of not taking coffee in the morning, had remained unaffected. But on the fourth day the symptoms became more serious. Soon after breakfast the persons affected began to suffer from vertigo, extreme lassitude, and feebleness; the sense of touch became so impaired that in carrying anything in the hand it was necessary to grasp the object very firmly to avoid dropping it, and the women were unable to sew. Vision also was so impaired that it was impossible to read; the pupils were markedly dilated. Alarmed by these symptoms, suspicion was at length fixed upon the morning coffee; but the coffee itself having been carefully roasted and ground in the house, the suspicion was directed to the chicory-root with which it was mingled in cooking. A fresh supply of chicory was obtained, and the symptoms disappeared. The suspected root was sent to Clouët for examination, who subjected it to very thorough tests. By chemical examination the presence of an alkaloid was discovered, which distinctly presented all the reactions of *hyoscyamine*. Moreover, through a microscopical examination, certain peculiarities of structure were found in portions of the suspected specimen of chicory, which were quite unlike anything appearing in pure specimens; but, on the other hand, corresponded precisely to the microscopic appearances found in the root of *hyoscyamus*.

The supposition was that in cultivating the chicory a few plants of the henbane had been overlooked, and that their roots were gathered with those of the chicory. If this be true, it is well to bear in mind the possibility of other such accidents occurring.—*Le Mouvement Médical*, Aug. 7, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

GEORGE F. SHRADY, A.M., M.D., Editor

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, September 25, 1875.

THE MEDICAL TREATMENT OF CONVICTS.

The publicity which has lately been given to the case of the convict Connolly, who was so cruelly beaten by the keepers of the Penitentiary, at Blackwell's Island, and the charge brought against Dr. Lenihan for neglect of duty in not attending to the patient as he should have done, will present the question of hospital management in a new light to the Commissioners of Charities and Corrections. The whole story, as told before the Coroner's jury, reveals a laxity of discipline in the care of the sick, which, were it intentional, we should say was exceedingly culpable. That such a state of affairs should exist with a management which is intelligent, painstaking, and conscientious, is strange, to say the least; but that the responsibility of any wrongdoing connected with this case should be shifted upon the shoulders of the unfortunate interne, either by direct charges or by implication, militates somewhat against our notions of ordinary fair play.

It appears that the physician in charge of the Penitentiary patients was summoned in the regular way to see Connolly in his cell. He responded to the call, examined him, and prescribed accordingly, leaving directions with the orderly that in case the patient was not better on the morrow to report the fact. The following day the convict was ordered to work by his keeper, and took his place in the gang. Being, as it appears, physically unable to perform his duties, he was beaten by those who were his overseers, and either as the result of the said beating, or of the progress of the chronic intracranial disease, or possibly of both combined, he was next reported, at the end of three days, in a dying condition in his cell. The physician was then duly summoned, when he found the patient past all hope of recovery.

The case naturally became one for the coroner, and the examination was conducted with all that sensational display which was calculated to appeal to the public

sympathy. The Commissioners were forced to take official notice of the matter, and very properly ordered an investigation on their own account. The keepers were placed under arrest in advance of any such action, and there seems to be no question in the minds of all acquainted with the facts that these men exceeded their functions as overseers, and merited not only prompt expulsion, but more positive punishment besides. So far, that part of the evil may be said to have been properly met.

The least that apparently could be done with the young doctor was a vote of censure by the Coroner's jury, and upon this hinged the investigation of his case by the Board of Commissioners, and this is the matter which concerns us more particularly in regard to the question under discussion. The Commissioners sent a request to the Medical Board of Charity Hospital to examine into the charges brought against the doctor, and report accordingly. At a meeting of the Medical Board, convened for the purpose, a committee, consisting of Drs. Walter R. Gillette, H. G. Piffard, and W. M. Chamberlain, was appointed to examine all the circumstances connected with the affair.

The result of this examination was, not only the exculpation of Dr. Lenihan, but a commendation for unusual attention to the prisoner, and resting the blame upon the overseers for not keeping him properly informed of the condition of the patient, in accordance with the directions. This report of the committee was unanimously adopted by the Medical Board, and afterwards sent to the Commissioners. It does not appear that the latter were inclined to be satisfied with the action taken by the medical staff, and indulged in some comments which were far from flattering to the intentions of the committee. The assertion by this committee that the convict received unusual attention was construed, by a strain at facetiousness, into sarcasm, and the question asked as to what constituted the usual care of such patients. To any one not acquainted with the fact of prison management at Blackwell's Island, these comments would seem to be fair criticism; but it is just to Dr. Lenihan to state that, in view of the surrounding circumstances, he did all that could have been expected of him, and was in no way to blame for the results. The fault rested entirely with the established method of prescribing for patients from the Penitentiary, and the extraordinary discretionary powers which the Commissioners seem willing to rest with the keepers. The physician has in reality no fair opportunity to perform his conscientious duty to these patients if the keeper chooses to interfere. The rule of the prison is, that the doctor shall attend to answer the sick call in the morning, and prescribe for such as are reported to him by the keepers. No record is kept of the case, which, it is true, is a fact to be deplored; but one which is excusable, considering the lack of the ordinary facilities for making such records. Under existing rules, and in accordance with the custom sanctioned by years of precedence, the physician has no occasion

to see any patient unless asked to do so by the keeper. Having done so, it is understood that his responsibility with the patient ends until the next summons from the keeper. Any attempt to keep a continuous charge of the patient is at the risk of an unpleasant conflict with the authority of the keeper, who is seldom if ever backward in openly ignoring the doctor's injunctions. In the exercise of the latter function the keeper is apparently supported by the prison authorities, any complaints of the doctor being considered of so trivial importance as not to require notice.

Now it seems to us that the time has come for the Commissioners to decide upon this question of authority, and give the physician a reasonable chance of doing justice to those who may be in need of his services. If that Board desire more than the usual care given to sick convicts on the part of the medical attendant, they should be ready to draw the line between his authority and that of the keeper; in a word, that the latter should have no right to exercise any discretionary power so long as a patient is under medical treatment. It is to be hoped that the medical board will take the opportunity, which this unfortunate case affords, of forcing such a necessity upon the authorities that be, if for no other reason than that the interne may not be held responsible for the acts of others over whom he now has no control.

A suggestion worthy of consideration in this connection has reference to the practicability of having a regular salaried physician attached to the Penitentiary, as is the case with other prisons, who should be vested with all the authority which usually belongs to that office.

THE PHARMACEUTISTS IN COUNCIL.

THE assembling of so large and respectable a body of educated men as has recently gathered in Boston, for purposes of practical improvement and mutual advancement, is worthy of more than a mere passing comment. So nearly allied are medicine and pharmacy that whatever interests or affects the one must of necessity cast a halo or a shadow around the other. We have frequently seen pharmacy quoted as the handmaiden of medicine, but there is something more of interdependence than such a relation of implied subserviency would indicate, and we are quite sure that the educated pharmacist feels that he now occupies a position in which his knowledge of the refinements of his art entitles him to a more elevated degree of prominence and consideration. Times are changed since the days of the Capulets, and a "beggarly account of empty boxes, green earthen pots, bladders, and musty seeds, remnants of packthread, and old cakes of roses," would hardly be a fair inventory of his stock in trade at the present day, when ornate and elaborate finish, and a dazzling display of showy bottles of cheap and costly perfumery, delicate articles of toilet adornment, gorgeous fountains of

marble, patent medicines of dubious efficacy, cigars of domestic and foreign manufacture, etc., etc., supplement, without displacing, the more reliable and substantial preparations of the Pharmacopœia. A few centuries ago the labors of the apothecary must have been herculean; no easy task could it have been to compound the senseless farragoes that were prescribed by the credulous physicians of those benighted times. Much as may be sometimes expected at his hands from some of the polypharmaceutical-prescription writers of these more enlightened days, we may well imagine the greater disgust that would be experienced by the modern pharmacist, if, like his ancient predecessor, he should be called upon to prepare mixtures embracing a score of such incongruous articles as characterized the recipes of those dark ages, when roots of a dozen kinds, goat's horns and brains, powdered bones of various birds and quadrupeds, pulverized gold and silver, animal excrement, etc., were heterogeneously commingled.

The attractive feature of these modern State and national pharmaceutical gatherings to all lovers of progress is the exhibition of a united effort towards refinement and a fair degree of perfection in education in the practical details of business, in the preparation of medicines, in the simplification of processes of manufacture and manipulation. It is to our interest, as medical men, to give them greeting in all their associate deliberations, and to wish them happy results in all their well-directed plans; for is not a great portion of their success in such fields of culture reflected upon the whole medical profession? We have one criticism, however, to make upon the modern nomenclature of the apothecary's science and art. It might admit of question whether or not the term "pharmacist"—literally, from its derivation (*φαρμακος*, a "poison" or a "medicine") a poisoner or a medical man, not necessarily a dispenser of poison or of medicine—is a desirable substitute for the respectable, and, from its antiquity, venerable name of "apothecary;" but we must unqualifiedly condemn the employment of the term "pharmacy," to designate both "the art of preparing, preserving, and compounding substances for the purposes of medicine," and the shop in which the labor is accomplished. The latter use of the word, although so employed in French, is manifestly a philological error.

A NEW PROCESS FOR STAINING TISSUES.—Mrs. Frances Elizabeth Hoggan, of London, says that the following process is chiefly of value because of the property it possesses of retaining the substance of the cell, as well as the nucleus and nucleolus, and because it gives the best results where the carminate of ammonia fails. It consists in first pouring over the specimen (after treating it with water and with methylated spirit) a one-per-cent. solution of perchloride of iron, and, in a few minutes afterwards, a few drops of two-per-cent. solution of pyrogallie acid—both solutions being made in distilled water.

Reviews and Notices of Books.

THE PROTOPLASMIC THEORY OF LIFE. By JOHN DRYSDALE, M.D., Edinburgh, F.R.M.S. London: Baillière, Tindall & Cox, 20 King William Street, Charing Cross.

THIS little volume, we are told by the author, was prepared for a work entitled, "Life and the Equivalence of Force," in which he designed to represent "certain views on the nature of life and other physiological questions contained in the partly posthumous works of Dr. John Fletcher." No claim is made to discoveries, and the opinions of writers are given in the form of extracts or full analyses. The special theory maintained in this book is, "that every action properly called vital, throughout the vegetable and animal kingdoms, results solely from the changes occurring in a structureless, semifluid, nitrogenous matter, now called protoplasm."

The author first discusses the theories of life now in vogue, giving the material and the immaterial ones at some length. Dr. John Fletcher is credited with being virtually the propounder of the protoplasmic theory, in his "Rudiments of Physiology," published in 1835. The various stages through which the cell-theory has passed are reviewed, from the time Schwann applied the term *cell* to animal life until 1854, when Max Schultze showed that the nucleus was not essential to the cell.

Hugo von Mohl is said to have been the first to use the term protoplasm. He applied it to vegetable cells; but Cohn, in 1854, showed that it was the equivalent in animal life of the sarcode of cells. Beale's protoplasmic theory of 1860 was, that "in the earliest visible speck of germ, up to the last moment of life in every living plant, animal, or protist, the attribute of life is restricted to one anatomical element alone, and this is homogeneous and structureless, while all the rest is merely passive and lifeless-formed material." This protoplasm is what Beale at first called *germinal matter*, and later *bioplasm*, it being the same in significance as *bioplasma*, a term recently proposed, *plasma* being said by Haeckel to be more correct than *plasma*.

This discovery was due, we are told, to the use of carmine, which stains the protoplasm, but leaves the other parts unaffected. That carmine, however, can be said to differentiate thus closely, would, we think, now be denied by most histologists.

The author devotes a good deal of space to anatomical questions, and it is easy to see that he is a faithful follower of Beale, though he feels himself compelled to state that that author's views have not always met with favor either in England or in other countries. In discussing the application of this protoplasmic theory to nerve and muscles, we observe that Beale takes distinct issue with those who believe that nerves have terminal organs. Later, however, his statements are modified so that he admits such bodies exist in the lizard and the chameleon, though he says the nerve-fibres really pass through them and end in loops. What becomes of the loops we are not told. In these as well as in other points, where he takes distinct issue with other histologists, he is exceedingly apt to neglect telling us on what reasons he bases his views. The last chapters in the book are devoted to the "Nature of Life," the "Connection of Force with Life," "Materialism," etc. He discusses the theories of Spencer, Bastian, and others, but avows that mod-

ern science has yet failed to disprove that the world was created. Between that which is living and non-living there is no easy gradation, but a great gulf. The author shows that he has had the literature of the subject at his command, though his practical acquaintance with the doctrines is probably limited. Those who are interested in the recent changes that have been made in these theories will find the book well worth reading.

Correspondence.

"UNSUCCESSFUL PRACTITIONERS."

TO THE EDITOR OF THE MEDICAL RECORD.

MR. EDITOR:—In the struggle for existence somebody is always getting pushed to the wall. It always has been so, and doubtless will always continue to be so. Some of these unfortunates drop out of the crush quietly; others signify their discomfiture by loud wails and lamentations, like your correspondent "Diploma." It matters little in what particular line this struggle has been, whether literature, science, art, trade, commerce, or manufacture, the burden of the wail of unsuccessful men is nearly always the same, viz., *that* particular calling is too crowded, and the great public too unappreciative; and those who have attained success have stumbled upon it, fallen into it, or been conducted to it by the wealth and influence of others. Unsuccessful men have ever modestly disclaimed any responsibility for their own failures.

Such being the case—and I believe you will concede the truth of my statements—I should not have taken upon myself to criticise the letter of your correspondent, did you not in your editorial upon the subject allude to it as "a very interesting, instructive, and suggestive letter," vouch for "the facts which he presents," favor holding the medical colleges to an accountability for overcrowding the profession, and inquire if "in the confusion of struggling multitudes, is there an even chance that the truly meritorious one will always succeed?"

Now, Mr. Editor, I am in no way personally connected with any of the medical colleges, nor interested in them save as institutions which have the training of our young men, and thus give character to our profession. On this account alone I cannot calmly bear to have them maligned.

Furthermore, I have always believed that honest and intelligent perseverance in *any legitimate* business will certainly bring success, unavoidable accidents alone excepted, of course. I believe it none the less firmly since reading "Diploma's" letter.

In the first place, *Is* the profession overcrowded? "Diploma" proves it to his own satisfaction, both by statistics and by his own experience. But then, anything can be proved by statistics or by personal experience. Personal experience has time and again proved conclusively the existence of ghosts and hobgoblins, has time and again proved insurmountable obstacles in the path to success, yet the great mass of mankind still doubt the existence of the former, and are quite unmindful of the latter. Success still comes to those who work for it, none the less than it did fifty or one hundred years ago.

That now and then a man fails to succeed in the practice of medicine proves nothing as to the vocation

being overcrowded. For one, I do not believe in this alleged overcrowding, but, on the contrary, maintain that the profession offers excellent promise of a livelihood and more, to young men of perseverance and ability.

I do not say that they will obtain it in the way which your correspondent has pursued. Upon his own showing, I think the responsibility for his failure can rest upon no one but himself. He had the best of advantages, and by all natural laws should have won in the battle for existence. But, with all the advantage which culture could give, on one occasion he was worsted by "a pair of pestilent, vulgar, and ill-educated quacks." Tell me of what advantage would it be to him to have the standard of medical education raised, when even the ill-educated quack has more *moral* control over patients than he?

Men have time and again tried vainly to legislate quackery out of existence—it is simply impossible. The educated physician has to compete with the ignorant and vulgar, always has had to, and probably always will, but who doubts the final issue? To argue anything but ultimate success, is to argue that the course of civilization is backward. So "Diploma's" few instances of successful ignorance may go for nothing. If I were disposed, I might cite numerous instances of honorable, intelligent, scientific men, who have attained success unaided during the time which "Diploma" has occupied in floundering, and, I fear, grumbling. In fact, "Diploma's" letter will be read by hundreds of men who will smile at what contradicts the lesson of their lives.

I believe as implicitly as "Diploma," or any one else, that the standard of medical education should be elevated, but not for his reasons. I do not believe that any course of study, either at Bellevue or in Germany, or anywhere else, can guarantee success to any man. Medical colleges may prepare a man for his battle, and the better they prepare him the better fight he may make if he will, but his success is always his own. It may be hastened or detained by wealth and influence; but without either, if he have the energy of a full manhood, he may attain it. I believe that the law of supply and demand alone can regulate the number of men who shall practise medicine, and that medical colleges are just as subservient to that law as individuals, and have no more control over it than individuals. Then let them do their work. Encourage them to elevate their standard for the public good, and not attempt it for private gain.

Jeremiahs will wail, but the world moves, and meritorious men will still succeed in the future as they have succeeded in the past.

I do not believe the professors of our colleges to be the men whom "Diploma" alleges. That many of them are honorable, high-toned men, I know; and the imputation that they graduate men merely for the money's sake is as base as it is groundless.

To sum up, then, "Diploma" is a disappointed man. He graduated at a first-class literary college, then at Bellevue—served eighteen months in hospital—went abroad for a year—returned—wrote articles for the papers, on which he was "complimented by many of the older members of the profession," etc., etc.—made a humiliating failure of his life—tells us all about it—and falls out of our ranks blaming everybody but himself, and warning everybody to beware of his example.

I will take up his warning, and admonish every young man studying medicine, about to study it, or just commencing to practise it, to beware of his example. Beware of his failure, and make your success certain.

Do not rest with the knowledge that you have an education "much more extensive than that usually enjoyed by students," and therefore think that you must succeed; but remember that with all his erudition he made a failure, while less trained men, by untiring energy and honest endeavor, have elevated themselves to places of honor and emolument.

SUCCESS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—To enter into the medical profession with brilliant hopes, given by good and thorough education, with much enthusiasm, patience, and perseverance, the whole backed up by a few thousand dollars, and meet with the disappointments that "Diploma" has had in practice, you must admit is more than sufficient to excuse his long letter with its series of complaints. He may console himself in thinking that he is not probably the only one whose hopes have been thus deceived, as no doubt the number of physicians exceeds by a great amount the requirements of our population. But if such is the case, he may ask, What is he to do? Medicine he likes; study he enjoys; and he hates to give up the medical profession, for which he has already done so much. I will say to him, then, there is a sister branch of medicine which is almost entirely overlooked in this country—which counts but very few amongst its regular members—whose interest is not less than the one he belongs to—whose scientific connections are equal to it—whose influences are no less beneficial (though in a different point of view), and whose financial rewards will, I have no doubt, be satisfactory to the most sanguine; in other words, let "Diploma" and his like unfortunate confrères give attention to Comparative Medicine, to *Veterinary Medicine*; let him become a scientific, graduated veterinarian, and I feel certain that in a very short time he will write you a different letter from that which was published in the last number of THE RECORD.

Yours truly,

M. D. V. S.

DIEULAFOY'S ASPIRATOR IN LITHOTRIPSY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Among the many examples given by Dieulafoy, where his method of pneumatic aspiration has been brought into requisition, he does not make mention, in his book published in 1873, of its having been employed as an adjuvant to lithotripsy. It has seemed to me that his valuable instrument, which is now in the hands of the great majority of surgeons, might be so employed with advantage, and replace the rubber "washing-bottle," of Clover, and thus diminish by one the already too numerous appliances in the surgical arsenal.

Having recently had an opportunity to demonstrate the excellence of this aspirator in the operation alluded to above, I have the honor, through your columns, to report the result to the profession, in order that the procedure may be further tested.

A few weeks ago I had occasion to perform lithotripsy upon an old man, suffering also from prostatic hypertrophy, who had for two years been compelled to rely almost entirely upon the catheter to void his urine. Immediately after the first sitting I proceeded to remove the fragments by first attaching to the end of a No. 12 evacuating silver catheter an india-rubber tube, two feet long, which led from one of the stop-cocks of Dieulafoy's inclined rack-and-pinion aspira-

tor. A single aspiration sufficed to abstract nearly all the detritus, and the whole process did not occupy two minutes' time. Owing to clogging of the rather small-bored tube, a second aspiration could not have been made without too much delay. To obviate this, I have since added to the apparatus a glass cylinder, so constructed as to receive the detritus and prevent its being forced either into the barrel of the aspirator or back into the bladder.

I believe that aspiration of calculous débris can be made much more safely and expeditiously by this means than by Clover's apparatus, and that it is especially applicable in cases where the prostate is so enlarged as to prevent the spontaneous expulsion of fragments or of small foreign bodies which may have eluded the lithotripter or other instruments for their extraction.

Very respectfully yours,

J. W. S. GOULEY, M.D.

311 MADISON AVENUE, NEW YORK, August 27, 1875.

GYNÆCOLOGY IN VIENNA.

TO THE EDITOR OF THE MEDICAL RECORD.

DURING the three months that I have spent in Vienna a good opportunity has been afforded me to see the large general hospital here, and the mode of conducting it, especially the departments of Midwifery and Gynæcology. I have thought a short notice of the latter might prove acceptable to the readers of THE RECORD, which I send you, together with the subjoined answers of Professor Gustav Braun to a series of questions propounded by Carl Derby, through the British embassy at Vienna, relating to the schools of midwifery in the Austrian empire, and intended for the use of the House of Commons, a duplicate copy of which Prof. B. has kindly furnished me.

In the first place, I would state that the general hospital of Vienna has three thousand and five hundred beds, which are divided and proportioned to the several departments of the University for clinical teaching, the arrangement differing in some particulars only from similar institutions of other countries.

The departments of Midwifery and Gynæcology, which alone receive from eight to ten thousand patients annually, and to which I now invite attention, differ more perhaps than the others in their details. For example, there are three of them, each having about one hundred and eighty beds—two for physicians and students, and one for midwives. To the former there are proportioned about thirty beds each, for the diseases of women are connected with the lying-in period. Prof. Carl von Braun is at the head of one of these, and Prof. Joseph Spaeth, at the other. At the head of the third is Prof. Gustav Braun, brother of the first-named, to whom I am under many obligations for his invitation to attend his lectures, and for the general information embodied in these remarks concerning the school of midwifery, of which he is in charge, with his able assistants, Drs. E. Welponer and C. Paulik.

Suffice it to say, my opportunities for seeing the workings of this department were most favorable, being allowed to enter the wards with the assistants at all hours of the day. Students from other departments are not admitted here, and visiting physicians only through invitation of the professor.

In the Austrian empire there are twelve schools for physicians, and twenty-six for midwives, fourteen of the latter being in Upper, and twelve in Lower Aus-

tria. The three principal schools of midwifery, however, are at Vienna, Prag, and Pesth.

From this statement it will be readily seen how much importance has been attached here to the teaching and training of midwives, which is now only beginning, it seems, to awaken an interest in countries other than those of continental Europe, where the system for so long a time has been more or less in vogue.

I found Prof. Braun's lectures most interesting, divested as they were of all technicalities, and brought within the comprehension even of the most unlettered of his class, which numbered about fifty. A large proportion of these women possessed more than ordinary intelligence, judging from their prompt answers to questions by the professor, and from the skill displayed by them while on duty in the critical wards, where there are from eight to ten deliveries daily.

Prof. B. makes his round daily at nine o'clock, and disposes of all critical cases that may have presented themselves during the night. It is not unusual to see three instrumental cases at this visit. I have seen him apply the forceps quite often, and he certainly does it with great dexterity, using generally Simpson's pattern, with a slight modification of the blades.

The great majority of these operations, however, are performed by the two assistants, whose experience, for young men, is something enormous.

After leaving the critical ward patients remain only two days, when they are discharged, excepting cases of course where there is some special complication, which are transferred to the ward set apart for them.

The rule in all cases is to give a dose of castor-oil on the third day. Peritonitis and perimetritis are treated usually with digitalis, quinine, salicine, and morphia injections, varied according to circumstances. Over the abdomen are laid cloths wrung out of water of the temperature of the room, and changed every half hour. For tympanites collodion is spread over the abdomen, to which Prof. B. attaches much importance from the compression thus afforded. In reply to a question of mine regarding the use of tinct. verat. virid., he said he seldom employed it, owing to its liability to disturb the bowels.

Prof. Braun informed me that he had met with only one case of rupture of the uterus within three years, and this one was not, properly speaking, of his service, having been admitted after the accident had occurred. He has within this period met with no accident of vesico-vaginal fistule, and only with very few of complete rupture of the perinæum. Superficial rupture is quite common, for which only two or three serre-fines are employed. The practice here in nearly all forceps cases is to make lateral incisions of the vulva, one to two inches on either side of the *fourchette*.

In conclusion, now, I have only to say that the Vienna School of Midwifery furnishes, according to my judgment, a most excellent model of organization and usefulness, and I earnestly recommend it to the notice of the profession. For many years I have myself been thoroughly convinced of the great necessity of such institutions in our own country, as a means tending to lessen the accidents of parturition, which I have so often been called upon to witness, as a result of the ignorance of our so-called midwives, both as regards the mechanism of labor and the peculiar circumstances demanding the presence of a physician; and equally long have I wondered why some of our medical institutions possessing clinical advantages have not taken the lead in organizing schools for this worthy object, so essential to the well-being of society in every community. Owing to the vast extent of many of our States and Territories, and the sparseness of the popu-

lation in many portions of the same, it would seem that the importance of the subject would be seen and felt everywhere. With one or two intelligent and properly trained midwives, in full accord with the physician of every neighborhood, who dare say that many valuable lives might not thereby be saved, and an incredible amount of suffering avoided? I can myself recall cases of frightful accidents presented to my notice for treatment, which could thus have been prevented, and, I daresay, other gynecological surgeons can do the same thing.

I will briefly state that the other two departments, under the direction of Professors C. Braun and Spaeth, for physicians, are conducted in a similar manner to the above as regards midwifery, the difference being mainly in the gynecological feature, which is also employed for clinical teaching. What strikes one in this connection as a little singular, is the smallness of the accommodations for diseases of women in a hospital so large. Prof. Carl Braun holds the first rank in the empire as gynecologist, and controls a very large practice, but he performs comparatively few of the capital operations, so to speak, in his branch. Nearly all of his cases of ovarian tumor, and many of vesico-vaginal fistule, he transfers to Prof. Billroth, the able Professor of Surgery of the University.

With regard to vesico-vaginal fistule, I found here comparatively little advance in its successful treatment, excepting through the doubtful expediency of kolpokleisis, recommended by Prof. Simon, of Heidelberg.

All operators here in this disease, so far as I can learn, as well as those throughout Germany, are his strict followers in this expedient, and perform it in a very large proportion of their cases. Even the few imitators in Germany of Sims, find it necessary also in a considerable number of their cases to resort to kolpokleisis.

This I consider a very interesting fact in connection with the treatment of vesico-vaginal fistule, and affords an admirable clue to the range of applicability of these two methods, as compared with my own.

My great object in visiting Germany has been to study this operation of kolpokleisis, and see, if possible, the advantages of it, so highly extolled by Prof. Simon. The results of my observations upon the subject so far are most interesting, based upon the experience of leading surgeons.

Through the kindness and liberality of Prof. Simon I had the opportunity last fall of testing with him, in the hospital, in a practical way, the applicability of our respective operations, in the face of obstacles regarded by him as insurmountable, excepting by his expedient of kolpokleisis.

In Vienna three similar cases have been presented to me for operation by Prof. Carl Braun, admitting only, according to his view, of kolpokleisis, and a fourth, thought by him to be incurable by any known method, owing to the complication of a large recto-vaginal fistule, situated twelve centimetres from the anus. Suffice it to say for the present, that in all of these cases I adhered to my standard of cure, namely, the coaptation of the fistulous edges and preservation of all the functions of the organs involved.

I hope soon to present my views upon this subject in a more extended form, and as the question at issue relates to the partial or complete unsexing of thirty per cent., at least, of all sufferers from vesico-vaginal fistule, its importance, in a practical point of view, I conceive, cannot be overestimated, and well deserves the serious attention of the profession at large.

The following are Prof. Braun's answers to the questions of Carl Derby already referred to:

"Every woman who wishes to enter the School of

Midwifery in the Imperial-Royal University in Vienna, must be able to read and write German correctly, and to cipher, and for this purpose she must undergo an examination for admission before the Professor.

"Married or unmarried women may be admitted, provided they are not more than forty-five years old (unmarried women must be twenty-four years old). In exceptional cases the Superior Department of Instruction permits younger single women to enter.

"The instruction is given at the clinic in the lying-in-hospital, where a University professor and two assistants are employed.

"The course of instruction is as follows:

"a. Systematic lecture of an hour's duration is delivered daily by one of the professors. The scholars are first shown the general anatomy of the human body, with especial regard to the female genital organs and the pelvis; then the organs in the pregnant state are shown; afterwards the attention is directed to the normal birth and child bed, and, finally, the pathological conditions are demonstrated. At each stage of the instruction the scholars are shown in which cases and at what time the aid of a physician is to be summoned.

"b. A course in which the lectures of the Professor are repeated by the assistants in turn. Each course lasts half a term, and five florins extra are paid therefor, while the instruction by the Professor is free. This course is not obligatory.

"c. The pupils are obliged to accompany the assistants in their visits to the lying-in rooms, where the separate cases are demonstrated, especially those in which the help of a physician is needed on account of illness.

"d. The scholars must assist at a certain number of births (at least ten), either in the presence of the Professor, the assistants, or the head midwife. When they are proficient they are allowed to take charge independently of special cases (always normal)."

It may be here remarked that in Austria in no case is a midwife allowed to use instruments, and she may only use manual help in the most urgent cases when it is impossible to procure the services of a physician.

"The course for midwives lasts from the first of October to the end of February, and from the first of March to the end of July. August and September are holiday months.

"During this time the scholars in classes must live in the institution, changing every eight days, making themselves generally useful.

"At the completion of the course the pupils must pass an examination before the Professor. If this be satisfactory they receive a certificate, by which they are admitted to the 'Strict Examination' (Rigorousum).

"The 'Strict Examination' is made by the Professor, the Dean of the Faculty, and a commissioner (who is a professional man), appointed by the government.

"This examination is absolutely necessary in order to obtain a diploma, and the fee therefor (without any exception) is twenty-eight florins and thirty kreutzer, Austrian currency.

"After the 'Strict Examination' is successfully passed, the midwives must take the oath prescribed by the Minister of Worship and Education—line 6938, March 6, 1874.

"In regard to the testimony of the midwives, their duties, and the punishment which they may undergo, see Instructions for Midwives, which were proclaimed by the Imperial-Royal Department of the Interior, March 25, 1875."

Very respectfully,

VIENNA, July, 1875.

NATHAN BOZEMAN.

New Instruments.

NEW DILATORS FOR THE CERVICAL CANAL, OR FEMALE URETHRA.

By H. T. HANKS, M.D.,

NEW YORK.

FIVE hard rubber rods, each about nine inches in length, constitute the set of dilators. Each rod consists of the body "A," five inches in length, and about one-fourth inch in diameter, as represented in the accompanying cut, separated by the shoulder "B" from the extremity "C," which is about two inches in length, and is the dilator proper. These extremities are rounded and curved, similar to Dr. Peaslee's metal dilators. The two dilators, one at each end of the rod, are curved, for convenience, in opposite directions. They are graduated in size, and numbered according to the American scale of bougies adopted by Van Buren & Keyes, and range from nine to eighteen inclusive.

The advantages claimed for these dilators are as follows:

- (1.) They are exceedingly light.
- (2.) They are easily kept clean, and will not rust like metal.
- (3.) They are readily bent when heated.
- (4.) They are more easily manipulated when in position and any version of the canal is indicated by the curve outside.
- (5.) The rods marked 9 and 10, and 11 and 12, make excellent cotton-holders.
- (6.) The rods being numbered renders it convenient to record the size of the canal.

(7.) The expense is but little more than half that of the metal dilators.

NEW YORK, Aug. 1, 1875.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Sept. 11th, 1875, to Sept. 18th, 1875.

MILHAU, J. J., Surgeon.—Relieved from duty at Willett's Point, New York Harbor, and granted leave of absence for six months. S. O. 183, c. s., A. G. O., Sept. 11, 1875.

SMITH, A. K., Surgeon.—Relieved from duty in Dep't of the Missouri, and assigned to duty at Willett's Point, New York Harbor. S. O. 183, c. s., A. G. O., Sept. 11, 1875.

HEGER, ANTHONY, Surgeon.—Relieved from duty in Dep't of Dakota, and assigned to duty at Willett's Point, New York Harbor. S. O. 182, A. G. O., Sept. 9, 1875.

HEGER, ANTHONY, Surgeon.—By S. O. 177, Hdqrs. Dep't of Dakota, Sept. 13, 1875, upon being relieved from duty by Surgeon Byrne, will comply with the requirements of S. O. 182, c. s., from War Dep't, relieving him from duty in Dep't of Dakota.

BYRNE, C. C., Surgeon.—By S. O. 177, Hdqrs. Dep't of Dakota, Sept. 13, 1875, relieved from duty at Fort A. Lincoln, D. T., and assigned to duty at Fort Snelling, Minn.; relieving Surgeon Heger, U. S. A.

BROOKE, JOHN, Assistant Surgeon.—To report in person to the Comd'g General, Dep't of the South, for assignment to duty. S. O. 182, c. s., A. G. O., Sept. 9, 1875.

BROOKE, JOHN, Assistant Surgeon.—By S. O. 132, Hdqrs. Dep't of the South, Sept. 13, 1875, to report to the Commanding Officer, Raleigh, N. C., for duty at that post.

MONROE, F. LE B., Assistant Surgeon.—Relieved from duty in Dep't of the South, to report to the President Army Medical Board, New York City, for examination for promotion, and upon its completion to the Commanding General, Dep't of Dakota, for assignment to duty. S. O. 182, c. s., A. G. O., Sept. 9, 1875.

BYRNE, C. B., Assistant Surgeon.—Relieved from duty at Willett's Point, New York Harbor, to report to the President Army Medical Board, New York City, for examination for promotion, and upon its completion to the Commanding General, Dep't of Texas, for assignment to duty. S. O. 182, c. s., A. G. O., Sept. 9, 1875.

HARVEY, P. F., Assistant Surgeon.—By S. O. 182, Hdqrs. Military Division of the Atlantic, granted leave of absence for one month, on surgeon's certificate of disability.

NAVY.

September 14.

NORTHFLEET, Assistant Surgeon.—Detached from special duty connected with the Darien Survey and ordered to the *Gettysburg*.

September 19.

BRUSH, GEORGE R., Surgeon, late of the *Saranac*.—Ordered to the Naval Hospital, Mare Island, Cal.

FITZSIMMONS, PAUL, Surgeon.—Detached from the Naval Hospital at Mare Island, Cal., and ordered to the Naval Hospital at New York.

THE "BASTIE" GLASS.—In order to correct the numerous incorrect statements that are being made concerning this new glass the *Chemical Review* says:—

1. The glass is not malleable, and is not claimed to be so by its inventor.

2. It is not unbreakable, though it is much tougher than common glass, and will bear a much stronger impact.

3. It is not annealed. It is only tempered, toughened, or hardened by its submersion in a hot oily bath.

4. It cannot be cut or engraved like ordinary glass. Flint and other glass can be cut and ground on the wheel, or by the sand-blast, throughout its entire thickness. Now, though a few specimens exhibited were ground by the sand-blast to a very slight depth, yet, if the blast goes beyond a certain depth, it will break into a thousand pieces, just as a Rupert's drop is shivered when ground.

5. It does not preserve its transparency after its transformation by tempering, as most of the specimens exhibited were only translucent. The glass is thus robbed of one of its chief beauties, rendering it unfit for any use where clearness and transparency are required.

6. The glass cannot be cut with a diamond, making it of little or no value for window-glass or photographic uses, both of which purposes frequently require the pieces to be cut more than once before exactly fitting the frame or the window-sash.

Medical Items and News.

A STATE MEDICAL SOCIETY IN ARKANSAS.—*The Daily Gazette*, published at Little Rock, Ark., on the 9th inst. contained the following notice, signed by two hundred and six of the leading physicians of the State:

"Experience has demonstrated conclusively that wisely conducted Medical Association inures to the development and growth of medical science. We, therefore, the undersigned, graduates in medicine, actuated by a desire to bury all the animosities engendered by the errors of the organization of 1870, and to avoid all occasion in the future for discord, and influenced solely by that which we consider as most vital to the wants and interests of the profession in this State, do cordially invite all other medical graduates of Arkansas, whose diplomas emanate from colleges recognized by the American Medical Association, to meet us in Mass Convention, at Little Rock, on Tuesday, October 12, 1875, for the purpose of organizing a Medical Society for the State of Arkansas. County Societies favorable to the objects contemplated by the Convention are solicited to co-operate by delegates selected for that purpose, in the proportion of one delegate to every five members. The representatives of County Societies will assume no priority in the Convention by virtue of their delegated authority, as it is intended that each physician present shall have an equal voice with all others in forming the organic law, and in organizing a State Medical Society in accordance therewith."

CATHETERISM OF THE UTERUS.—Prof. Simon, of Heidelberg, the advocate of passing the hand into the rectum and colon, for the purpose of diagnosis, proposes a method equally bold in investigating affections of the ureters and kidneys.

In No. 88 of *Volkmann's Sammlung*, after describing the circumstances under which it is desirable to dilate the female urethra (so that the finger may be carried in and the bladder explored), and to perform the vesico-vaginal section, he states that this latter operation may be taken advantage of for catheterizing the ureters. He has himself done this seventeen times on eleven women, and has been enabled without the slightest difficulty to reach the pelvis of the kidney. As yet he has had no opportunity of employing this procedure in a case of disease, but believes it will be found useful in the diagnosis and treatment of calculous affections; calculi in obstructed passages might be extracted or cut out, and so forth.

THE NEW BUILDING OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.—In *THE MEDICAL RECORD* of May 29th we mentioned the commencement of the new building which the Medical Department of the University of the City of New York have found necessary to erect in order to accommodate their increasing classes and their needs for giving instruction. The work has now been completed, and on Monday evening, the 13th inst., the faculty received the friends of the school and showed the rooms and the appliances for teaching.

The new building is situated on Twenty-sixth street, directly opposite the entrance to the grounds of Bellevue Hospital, and covers an area of sixty by one hundred feet. It consists of four stories and a basement, which are arranged in the following manner:

Through the centre of the first story a broad, marble-floored hall runs the entire length of the building. At the further end of it an imposing staircase leads to the level of the third floor, and furnishes the entrance for students to the lecture-room. On either side of the

hall are rooms for the Dean of the Faculty; for the examination of patients who attend the college clinics; for the janitor and his family; for the museum, and also a sitting-room for students.

On the second floor are a number of private rooms for the different professors, but the greater part of this story is occupied by the lecture amphitheatre, which is at the back of the building, and reaches from the floor of the second to the ceiling of the third stories. It is provided with iron opera-chairs, arranged in semi-circles, and having backs and seats of narrow strips of hard wood. The seats are made to tilt up out of the way when unoccupied, and will accommodate about three hundred and fifty listeners. A laboratory for illustrating chemical and physiological lectures is in the rear of the lecturer's desk, and to either side of it, and opening into the lecture-room, are waiting-rooms for professors and patients, the latter having a supplementary room for physical diagnosis. Under the ranges of seats are rooms for undressing and anesthetizing patients, and where they can be cared for after operations until they are in condition to be removed.

The third, or half-story, contains additional rooms for the faculty, and a large working laboratory for chemical and physiological classes, to which is attached a room for work, which requires the exclusion of sunlight.

The dissecting-room occupies the greater part of the fourth, or upper floor, and is well supplied with all the conveniences essential to the comforts of those who may be studying practical anatomy. In the rear of this dissecting-room are the laboratories of the professors of Toxicology and of Diseases of the Skin.

Occupying fully one-third of this floor is the private laboratory of the professor of Physiology and Pathology, like which, for completeness, we have nothing in this country and but few abroad. Besides a private hallway and an office, separate rooms are provided for electro-galvanoscropy; for spectroscopy; for physiological chemistry; for fine glass apparatus and scales; for reduction of organic and other bodies, and for gas generators; for photography; for the care and observation of animals, and for microscopic work. The completeness of the appointments of the building throughout won the unqualified admiration of the large company of physicians who were present, many of whom have still a vivid recollection of what medical schools were in the days when the professor sat at his desk and read, not always in an audible manner, his lecture from the pages of a well-worn manuscript. When, aside from the simple experiments of the lecture on chemistry, and the passing around of a few dubious-looking drugs by the professor of materia medica, almost nothing was attempted in the way of illustration, and but little, if any, more in the field of clinical instruction.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

Monday, Sept. 27th.—Med. Soc. of the Co. of N. Y.. Nomination of officers.

Tuesday, Sept. 28th.—Adjourned Annual Meeting of the Alumni Association of Bellevue Hosp. Med. Col., at the rooms of the Academy of Medicine.

Friday, Oct. 1st.—Medical Library and Journal Assoc. (first meeting of the season).

Monday, Oct. 4th.—N. Y. Neurological Society, College of Phys. and Surg., cor. 23d st. and Fourth av.

Thursday, Oct. 7.—N. Y. Academy of Medicine, 12 W. 31st st.

Friday, Oct 8.—N. Y. Medical Library and Journal Assoc., 107 E. 28th st.

Original Communications.

REMARKS

ON ARTIFICIAL RESPIRATION.

SUGGESTED BY TWO IMPORTANT CASES LATELY PUBLISHED.

By BEVERLEY ROBINSON, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL (DEPARTMENT OF THE THROAT), ETC., ETC.

No one doubts the usefulness of artificial respiration as a means of restoring consciousness in cases of asphyxia. Numerous instances of new-born children in an almost inanimate condition, of individuals who have nearly perished by drowning, or in consequence of the absorption of noxious vapors, and who are thus brought back, as it were, to life and health, sufficiently demonstrate its efficacy.

Owing, however, to a want of accurate limitations in regard to the manner of performing it, and of knowledge with respect to the exact conditions when it is imperatively needed, its use has hitherto been too much restricted. Indeed few practitioners have employed it in the treatment of other asphyxie states than those resulting from the causes above mentioned.

Within a brief period, however, in our city, attention has been directed towards it in an unusual degree. In the April number (1875) of the *New York Medical Journal*, two cases—one an example of accidental poisoning with aconite, the other with laudanum—are graphically portrayed by Dr. John Ellis Blake. In both instances respiration was continued by artificial means; and in one—thanks in great measure to the laudable and persistent efforts of the medical gentlemen in attendance—a remarkable recovery of the patient followed their use. In the case now referred to (poisoning with aconite) "respiration could only be excited and kept up by artificial means for some hours, of which means the galvanic current was the chief, the all-important one," and the patient is stated to have been "without any trace of pulse for a period of over three hours."

Are cases of "accident or emergency" the only ones where artificial respiration may be put in requisition as a means of cure when life is imminently menaced? Evidently not, for several instances of acute disease (pneumonia, diphtheria, etc.,) are already on record in which death was apparently close at hand, and where, by the introduction of air into the lungs, a rapid change for the better has ensued.

On one occasion simple atmospheric air was employed; on another, air was uningled with a large proportion of oxygen gas.

And no further back than July 17th, do we find registered in the *London Medical Times and Gazette*, "a recovery by artificial respiration after tracheotomy in a case of diphtheritic croup."

In the case reported by Dr. Richardson, the double-acting bellows was put in requisition by the inventor at a period when the child had "ceased to breathe altogether, and to common observation appeared to be dead." Certainly the interest pertaining to the *historics* quoted, and the intrinsic importance of the *subject*, will render a few remarks on them and it *not* out of place at this time. The means employed to stimulate arrested respiration may be divided into—1. Ordinary, viz.: inhalation of some pungent vapor, external friction or castigation, tickling of the fauces, hot-baths, sinapisms, bleeding, etc. 2. Exceptional, viz.:

insufflators, or bellows of different sorts; the galvanic current, one of two methods known as Marshall Hall's "ready method" and Dr. Silvester's "method."

Those in the first division are in too familiar use to merit any remarks. Marshall Hall's "ready method" and Dr. Silvester's method are to be ranked among the common property of the profession, and the manner of conducting them is known, at least in theory, to all of its members. They are much too recommendable to be thrown completely aside as yet, and have often done good service in the cause of humanity; and of truth it would seem as if the mere gentle rolling of the body, stretched at length in the facial decubitus, from this position to either side with rhythmic regularity, and back again to its original situation, could scarcely produce either the rupture of lung or vascular tissue.

As such may be said of Dr. Silvester's method, where the expansion and falling back of the chest-walls is effected by raising up the arms in a flexed position and then successively and with pressure approaching them to the sides of the thorax.

One objection has been urged to the *general* adoption of one or other of these methods, even while their great and signal benefits in a large number of instances have been widely recognized.

It is affirmed that they interfere with the movements of the heart, and Dr. Benjamin W. Richardson notably expresses himself in the following terms: "I find by experiment that when the heart is brought down to a very feeble action, from suspension of the respiratory power, the slightest thoracic pressure is sufficient to arrest action altogether (*Medical Times and Gazette*, December 4th, 1869). Surely such an assertion, coming from so distinguished an authority, should make us chary of these or analogous methods of restoring suspended animation (*vide* "Speedy Method" in Asphyxia, *THE (NEW YORK) MEDICAL RECORD*, July 31st, 1875) in cases where the action of the heart is very weak or apparently stopped. And even in instances where the pulse is still readily perceptible at the wrist, and the heart-sounds only somewhat diminished in force, we cannot exercise too much care in avoiding to put undue weight upon the parietes of the chest. Besides, by so doing would we not show ignorance of a physiological fact already well known to all?

Lung tissue contains elastic fibres, and the action of these is sufficient, even though death has supervened, to enable the walls of the alveoli to come back upon themselves, and to drive out a portion at least of the residual air contained in them.

The action of the heart, as well as that of the lungs, may also be completely abolished by the employment of the galvanic current, unless it be very sagaciously applied.

For let us consider a moment what is the usual way of using it in those instances where it would appear to be imperatively called for. One electrode is put on the side of the neck, and the other in the epigastric region, near the costal insertions of the diaphragm.

They are placed, we perceive, so as to bring the stimulating action of electricity as nearly and directly as possible upon the nerve-trunks and plexus which hold the respiratory function under their control. Now in the lateral cervical region the grand sympathetic and pneumogastric are situated, and also the branches of the cervical and dorsal spinal nerve (including the phrenic), which animate especially the inspiratory and expiratory muscles. Beneath the anterior insertions of the diaphragm lies the solar plexus, which receives branches, as we are aware, from all the following nerves, viz., the vagus, sympathetic, and phrenic.

What does modern physiology teach us in this connection?

If we stimulate *gently* the trunk of the pneumogastric, or the intact cardiac nerves of the sympathetic, the heart's action is increased, its movements are accelerated. If, on the contrary, the stimulation of either of these nerves is too energetic, the inevitable consequence is that the heart-beats become slower, and in diminishing in number they lose their energy, and to that point oftentimes that they stop altogether.

An energetic stimulation of these same nerve-trunks, will likewise occasion stoppage of the respiration. These facts are explained by the assertion that the action of the nerves referred to, when *gently* stimulated, may be considered as being direct or centrifugal. The action of these same nerves, when it is obtained by energetic stimulation, is complicated with phenomena which are due to reflex action, viz., to an action which takes place in the centripetal direction, reverberates violently upon the nervous centres, and occasions phenomena of characteristic depression.

In one of the cases reported by Dr. Blake, "the current was very strong, strong enough at each application to twist the neck and body to one side, yet it utterly failed at one time, during the first hour, to excite respiratory action." After what we have said of our physiological teachings, one of the evident causes of the failure, is readily found in a more than sufficient use at the time mentioned of the galvanic current.

The obvious deduction from what we have written is, that *the galvanic current, when put in requisition in cases of suspended respiration, should be used with a feeble current, and that a powerful current can but prove in a certain measure injurious, and may become fatal.* There remain to be considered by us certain conditions which attach themselves to insufflation of the lungs.

This may be accomplished by placing our mouth directly over that of the patient, and endeavoring to dilate his chest by breathing air into it. It is a method which, though occasionally successful, is not an agreeable one to the attending physician, and for this reason we deem it more advisable to use an insufflator. This instrument may be introduced into the larynx through the mouth, and inflation of the lungs can thus be performed with tolerable success.

Unfortunately the employment of the insufflator is open to the serious objection of blowing air rendered impure by an excess of carbonic acid and organic particles into the patient's lungs. The double-acting elastic hand-bellows appears to us therefore to be an advantageous substitute for the insufflator.

It is more bulky, however, and cannot be carried as our insufflator can, in the pocket-case of the practitioner THE (New York) MEDICAL RECORD, April 3, 1875).

On the other hand, if we make use of the "bellows," the amount of air insufflated in a given period of time, may always be approximatively known, and the supply of fluid to make it efficient, can *always* be drawn from the atmosphere. Besides, by referring to the description of Richardson's apparatus (*Medical Times and Gazette*, December 9, 1869), we shall perceive that it is possible to get rid of the residual effete air which would otherwise remain in part in the pulmonary vessels.

In the first case reported by Dr. Blake, we are satisfied, upon careful perusal, that the employment of oxygen incorporated with atmospheric air has been of very great value.

We would suggest, however, that in another analogous instance where it would be well to make a trial

of it, the proportionate amounts of air and gas might be regulated in such a way as to make the experiments more accurate, and in this manner of greater practical utility to those physicians who desire to test its efficacy.

This may be readily accomplished by attaching a piece of india-rubber tube to either nozzle of a cylinder containing oxygen or atmospheric air, under an equal degree of pressure.

The further ends of the two tubes should be made into one, so as to fit on Richardson's bellows. If we pursue this plan, bellows and cylinders could be easily connected, and by tuning the stopcocks of the cylinders to a given point, a determined quantity of fluid would be permitted to escape from each cylinder into the bellows. The bellows may then be pressed after the customary manner.

Due precaution is of course to be exercised so as not to force too large a volume of this mixed fluid into the lungs during a given time, nor is too great pressure ever to be used. Great moderation in both particulars must be shown, otherwise bad results may quickly follow, among which generalized vesicular emphysema of lung, or even rupture of vascular walls, are not to be lost sight of. The insufflations should not be continued too long, and so soon as there is evidence of returning contractility in the voluntary respiratory muscles, they may be intermitted, and only resumed when necessity demands it.

37 WEST THIRTY-FIFTH STREET.

REPORT OF A CASE OF RECURRENT TUMOR OF THE NECK,

WITH SOME REMARKS ON THE ELECTROLYTIC TREATMENT OF TUMORS.

By E. T. COMEGYS, A.M., M.D.,

ASSISTANT SURGEON, U.S.A.

C. C., æt. 34, American, merchant, states that about five years ago he first noticed a small tumor in the left side of his neck, just behind the angle of the jaw. There exists no family history of cancer or of any kind of tumor. The tumor, diagnosed as a fibroid, was removed, partly by the knife and partly by caustics. About a year afterwards the tumor recurred, about two inches below its first site, and was removed with caustics. Two years after this it again recurred, this time at the root of the neck, and was removed by the same means (the patient being for the last two times under the treatment of a "cancer-cure doctor"). About two years after this the tumor (still diagnosed as a fibroid) reappeared just over the clavicle, and the patient came under the treatment of a homœopathist, who attempted to dissipate it by electrolysis, using the interrupted current. Up to this time the tumors had all been small (none larger than a walnut). At the beginning of the electrolytic treatment, this one was about the size of a hazel-nut, and freely movable under the skin. This treatment was continued for about three months, during which time the tumor steadily increased in size, invaded the bone, and ulcerated around the points of insertion of the needles. The patient, being dissatisfied, now consulted a regular physician, who, diagnosing it a recurrent fibroid, determined to excise it, and kindly invited me to assist him in the operation and after-treatment.

The prominent points in the previous history of these tumors are: *recurrence after removal, very slow growth, absence of pain, absence of enlarged blood-vessels around the growth, and absence of cachexia.* Even at this

time the only symptoms of malignancy which it presented were recurrence after removal and (only after the use of electricity) occasional pains in the shoulder.

The growth was excised, together with three inches of the clavicle, to which it was firmly attached. It was unfortunately thrown away before a piece for examination under the microscope could be obtained. It reappeared in about three weeks, at the end of the outer part of the clavicle, and was again excised, this time with the rest of the bone. Erysipelas developed in the arm a few days afterwards, followed by abscesses, the discharge from which finally exhausted the patient, and he died about four months after the last operation. An examination of the tumor under the microscope (after its last removal) showed a fibrous stroma, with a few of what Dr. J. J. Woodward, U.S.A., calls the small brood cancer-cells.

In connection with the treatment of this case two questions arise for consideration. 1st. What is the relative value of electrolysis in the treatment of tumors? and, 2d, May not its use, from the irritation it produces, convert a benign into a malignant growth?

1. There are very few reported cases in which electrolysis has been used, and the results vary very much. Althaus speaks of fifty-eight cases, eleven of which were malignant and forty-seven non-malignant. Of the non-malignant ones there were twenty-seven cures (all small tumors and principally sebaceous ones); ten improved, and in seven (the largest of all) no result. Of the malignant ones two were successes and nine not. Mr. Callender, of London, reports several cases in which sloughing of the tumor was produced, and increased growth after the use of electricity was stopped. These are, of course, not all of the reported cases, but the others are so similar that it is unnecessary to mention them. The results of these cases show that electrolysis has only removed a few small, unimportant tumors, and a few small naevi. It has, almost without exception, failed whenever used in large growths. As a method of treatment which does away with the knife (and one which can be used at times and in places where the knife cannot) it is certainly of value; but, even under the most favorable circumstances, it is an uncertain, and sometimes even a dangerous remedy. Uncertain, because it so seldom succeeds, oftener wearing out the patience both of physician and patient—dangerous, because it so often causes sloughing, the products of which cannot be at once removed, and hence exposes the patient to the dangers of septicæmia, etc., for a longer time than if the knife had been used.

The principal other methods of treatment are by caustics, ligature, and the knife. As for treatment by the knife, its advantages are too well known, and it is so much used that it needs no discussion here. Treatment by caustics and the ligature are both open to the same objections—they produce a sloughing sore with its possible consequences, and are very painful and tedious; indeed, they are now seldom used when the knife can be.

2. The action of the electric current on the human body is chiefly stimulant and tonic, and, when used for electrolysis, also decomposant (the constant current differing from the interrupted only in intensity), and there must necessarily be some irritation from the introduction of the needles. The elements of tumors (particularly cancerous ones) are of low vitality, are apt to ulcerate and degenerate, and particularly are they apt to grow when irritated, and to assume a malignant type. This is so well recognized that Jonathan Hutchinson, of London, has published a paper in

which he shows how an innocent tumor may, by proper irritation, be converted into a malignant one, and those who believe in the *local* origin of cancerous tumors contend that always, in the history of one, will there also be found that of some antecedent injury to, or other irritation in, the part where it first appears.

In the history of this case *two* facts are to be noticed—1st, that the *interrupted* current was used for electrolysis; and 2d, that while under this treatment the tumor steadily increased in size, invaded the bone, and began to give evidences of having become cancerous. (It is to be regretted that no microscopical examination of it was ever made previous to its removal for the last time, but its general history was not that of cancer. When it was removed for the last time the microscope showed very plainly that it had become one.) May this not have been the result of the stimulation and irritation caused by the use of electricity?

Its history hitherto had only resembled that of cancer in its recurrence after removal, but from the time that the electrolytic treatment was instituted, it began to resemble it in almost all other points (rapid growth, pain, cachexia, etc. [the cachexia did not appear until about six weeks before his death]). Benign tumors of any kind, particularly recurrent ones, are apt from irritation to become malignant, and even in parts of the body previously healthy malignant growths arise from irritation, as, for instance, epithelioma of the lip from smoking, and "chimney-sweep's cancer" of the scrotum from the irritation of the soot. Now, the principal action of the interrupted current is stimulation; it is only feebly electrolytic, and there was a good deal of irritation from the introduction of the needles. Here were all the favorable conditions necessary: a recurrent tumor (probably on the point of degenerating into a malignant one) and decided stimulation and irritation. One conclusion, therefore, that may be drawn is, that this electric treatment converted this recurrent fibroid into a malignant tumor, or, at least, very much hastened its degeneration into one. Another is, that electrolysis should only be used in the treatment of tumors when they are very small, or are inaccessible to any other method.

FORT WADSWORTH, N. Y. HARBOR.

CLOSE QUARTERS.—At West Lowe, in Cornwall, Eng., over eight thousand bodies have been interred in something more than half an acre of land, which has actually swollen up into a hill, leaving the church in a pit.

According to the writer in an English journal, putrefying bodies lie together through the soil like plums in a pudding, and when a new candidate for admission appears, exploring parties go out with an iron rod and take soundings till a firm space of four and a half feet is discovered. A horrible slime is said be constantly oozing from the graves in the higher part of the yard, which runs into the floor of the belfry, and disinfectants have to be used for the safety of the ringers. Fresh primroses gathered and placed in the church for purposes of decoration on Easter Sunday, turned almost black by the following evening, owing to the presence of sulphuretted hydrogen in the atmosphere in such quantity as to become dangerous to human life. On Ash-Wednesday the air of the church was so fetid that the congregation were unable to remain until the end of the service. The vicar and the government inspector desire a change, but the rate-payers, who apparently have the authority, think the present arrangement good enough.

SUBACUTE GASTRITIS FROM THE INHALATION OF BED-BUG POISON.

G. A. BAXTER, M.D.,

CHATTANOOGA, TENN.

M. B., aged twenty-four, lawyer; healthy, robust constitution; of good habits, and in every respect temperate, came to me July 18th, 1875, complaining of some uneasiness in the epigastric region and in the kidneys, with burning pains in the former, with tympanitis, tenesmus, increase of temperature, congested eyes, some giddiness, etc. Believing it to be only some slight derangement of the digestive organs or torpidity of the liver, I advised him to remain in my offices a day or two for treatment, which he did. I gave him one or two three-grain doses of calomel followed by a purgative. For a day or two he did very well, and went back to his own offices for business on the 20th July, 1875.

July 21st. Suddenly attacked again. Violent pains in epigastric region, high fever, intense headache, great tenesmus, abdomen very tympanitic; skin hot and dry; tenderness very marked over the epigastric region; pulse marked by increase in rapidity, but full and strong; considerable thirst, vomiting, soreness in region of kidneys, etc. I removed him to my own rooms again, where he could receive better attention. Placed a large mustard-plaster over his stomach. Gave him an active purgative, with a full dose of Dover's powder, the last for its diaphoretic and anodyne effects combined. He soon fell into a quiet easy sleep. The following day he was considerably improved; pulse still high, vomiting occasionally, considerable tenesmus and tympanitis, great tenderness remaining, and headache severe. Ordered tinct. aconite and spts. æth. nitrosi, with pulvis Doveri at intervals, as necessary for the relief of pain, and counter-irritation at intervals, as could be borne, with blistering.

July 25. Continued improvement until to-day, when I discharged him from further treatment, though considerable soreness remained.

The chief point of interest in this case remains to be told. In searching for a cause for the epigastric disturbance, I could find none in his habits, in his constitutional tendencies, in his surroundings or food taken, until he himself suggested a probable cause in the inhalation of some bed-bug poison he had been using in his bed room. On closer questioning I found that he had been using an aqueous solution of corrosive sublimate, very strong. He had commenced the active use of this the day previous to his first attack, spreading it over his furniture freely, especially his bed. He smelt it very strong that night when he retired. He had caused it to be used very freely ever since. On going to his room I could still detect the smell of hydrochloric acid gas, and I could not but be persuaded this was the true cause of the disturbance. During his stay in my office he had been free from its influence, and had rapidly improved. On returning to his own, and to this influence, he had been attacked again. I advised him to have his rooms thoroughly cleansed and ventilated, and he has not since been so troubled.

HEMATURIA FROM A STRAIN.

J. L., negro, healthy and strong, iron-worker, aged 45, consulted me July 15, 1875, for hæmaturia. Passed in my office fully a half-pint of urine and blood mixed; the blood so thick that it clotted after being passed in the vessel, in part, some of it being in

small clots when passed. He gave the following history of his injury:

Monday, July 14th, while lifting heavy cinders he had felt a sharp pain in the small of his back and lower portion of his bowels, and remarked that he had injured himself seriously internally. Continued work however, as the pain ceased almost as suddenly as it began; but in an hour or two, grew so faint that he had to stop work for the day. He consulted two physicians, and remained under their charge until Thursday morning, when he discharged them, having received no benefit he said, and applied to me. He affirmed that he had been passing blood just as freely as he had shown me, and I have described above, from Monday morning until that time.

I placed him immediately upon twenty-grain doses of gallic acid every two hours, and instructed him to go home and lie down. Instead of doing this he walked the distance of a mile and continued work. I did not see him until four that afternoon, and in the meantime he had consulted a physician in the neighborhood of his work, Dr. A. S. Wilsie, who had cupped him over the kidneys. Four o'clock P.M., bladder full and distended with urine and blood. Very weak, thought he had passed more blood to-day than usual. I drew from his bladder fully a quart of urine and blood, much more of the former however, I think, as there was now no clotting in the vessel. Washed out his bladder thoroughly with warm water and injected it two or three times with a strong solution of tannin and catechu. Ordered a continuance of gallic acid, increasing the dose to thirty grains. I have since learned that previous to coming under my charge he had taken 100 grains.

July 16th. Showed decided improvement, but very weak, more so than day previous. Continued gallic acid in same doses, with the addition of quinine five grains a day.

July 17th. Still improving. Urine almost clear. Feeling better in every way. Complains of a tickling sensation over the whole body. Washed his bladder out thoroughly. Ordered a continuance of same treatment, with instructions to send for me if needed again.

July 19th. Discharged from treatment recovered.

This man had taken, previous to the 15th, 100 grains gallic acid.

July 15th. He took 60 grains.

July 16th. He took 128 grains.

July 17-19th. He took 50 grains.

Making in all, 430 grains before recovery.

The difficulty in the case lay chiefly in an accurate diagnosis. The character of the pain, which was very slight and hardly to be located in any particular spot, as he described it, giving me no correct clue to the seat of the difficulty. I was at first undecided whether the blood came from the kidney or bladder. Hence, beyond simply washing his bladder out with water, I took the precaution to inject it with a strong solution of tannin and catechu. I am satisfied now, however, more from the line and result of treatment than anything else, that the lesion must have been in the kidney; probably the rupture of some capillary which poured its contents into the ureter.

PRIVATE FREE DISPENSARIES IN VIENNA.—Vienna medical men are very much excited just now over the question of private free dispensaries as a mode of advertising the specialties of their originators, and the medical journals are warily denouncing these institutions.

POSITION IN SHOULDER PRESENTATIONS.

By E. R. MAXSON, M.D., LL.D.,

SYRACUSE, N. Y.

I PUBLISHED through *The Medical and Surgical Reporter*, in 1867, an account of a discovery which I made about seven years before, in relation to the treatment of *shoulder presentations*.

In the article referred to I stated as plainly as I could the circumstances connected with and leading to the changing of this abnormal to a perfectly natural presentation, *without risk to mother or child*, by placing the woman on her knees, on pillows of folded quilts, with the head and shoulders low, as suggested by Prof. T. G. Thomas to return prolapsed cord.

I stated in said article that it was while replacing a prolapsed cord, with the woman in that *position*, that I corrected an abnormal presentation, by the *position* and slight manipulation attending the replacement; and that from this circumstance I was induced to try this *position* in a bad shoulder presentation, in which I was entirely successful, gravitation doing most of it, I simply following the receding shoulder with my hand, grasping the vertex and bringing it into the superior strait, removing the hand after two or three pains had engaged the head, and the woman had been laid down on the left side, etc.

During the seven years I was testing the feasibility of this method, *for every case*, before publishing, I had suggested it to many prominent obstetricians, and had also given my experience in the matter before the Ontario County Medical Society, of which I was a member. And during the summer of 1867, while in Europe, I stated my observations and experience in the matter to Professors Leishman, Sir James Y. Simpson, and many others, all of whom appeared to appreciate the vast superiority of my method to *turning*, as being attended with no risk to mother or child, and very trifling inconvenience, that of *position*, and for not longer than from three to five minutes, or even less. In fact, so impressed was Sir James with the superiority of my method over the ordinary one of turning, that he insisted that I should write my Essay on Shoulder Presentations, "*explaining it*," for the International Medical Congress in Paris of that year, to which I was a delegate; and though I had prepared an essay on another subject, I complied, writing it while in London, and presenting it instead of the other, as he requested and insisted, telling me it was "the best thought I ever had," etc. And though Sir James showed me directions in an ancient German obstetrical work directing the *position* recommended by Prof. Thomas for returning prolapsed cord, which Thomas had never seen or heard of, as it had been forgotten; in making this position available for changing shoulder into a natural presentation. Sir James declared I was "ahead of them all," saying that he should "advise and practise it" thereafter.

And as it had been published in *The Reporter*, of Philadelphia, copied entire into the *Boston Medical and Surgical Journal*, and from that entire into at least one large obstetrical work, and referred to as an important American obstetrical discovery by Prof. S. D. Gross, in his Introductory, in the autumn of 1867, which was published in pamphlet form and distributed extensively in this country and abroad. I did suppose that it had become the established practice with intelligent obstetricians everywhere, as I know it is with many in this country and abroad.

But recent intelligence of children that have been sacrificed, and mothers imperilled, by the old method

of *turning*, has convinced me that many may not as yet have availed themselves of *position* for changing shoulder into natural presentations, either because they may not have been informed, or else, having been posted on this subject, they have been incredulous, and slow to accept so simple, safe, and common-sense a method for a long established, formidable, and more or less dangerous one for both mother and child, even by the most skilful and prudent hands. And this must be my apology for thus *again* calling attention to the treatment of shoulder presentations.

No. 208 MADISON STREET, SYRACUSE, N. Y., 1875.

Reports of Hospitals.

BELLEVUE HOSPITAL.

REPORTS OF PRACTICE AND PECULIARITIES OF TREATMENT.

PHTHISIS—PNEUMO-HYDROTHORAX.

A CASE of this affection exhibited some features of interest which will be noted as the history is given.

A female patient, *æt.* 30, with nothing of special importance in her previous history, was admitted to the hospital Aug. 6th, complaining of illness of long duration, but without definite ailment. She was considerably depreciated with respect to her general strength, and had a cough of very moderate severity, which was attended with more or less expectoration. When admitted, her temperature was 101° F., and evidences were found of lung consolidation, moderate in extent, at the upper anterior portion of the chest upon both sides. Associated with this was a slight amount of chronic laryngitis, which was regarded as one point of significance in the case.

The next day after admission the patient was seized with a severe lancinating pain in the right axillary region, and her temperature quickly arose to 105° F., and her respiration soon numbered fifty to the minute.

Her distress was intense, and a hypodermic injection of morphine was at once administered, which afforded some relief.

Upon the following day the temperature fell to 99½° F. at one hour, but in the main stood at 102° F.

There was another point of interest, namely, the comparatively quick subsidence of distressing symptoms, showing how readily in some cases the system and respiratory function accommodate themselves to the condition of lung and pleural cavity.

Aug. 9th,	P. 100,	R. 36,	T. 101½° F.
Aug. 10th,	P. 100,	R. 36,	T. 101° F.
Aug. 11th,	P. 126,	R. 36,	T. 102° F.

The respiration up to Sept. 13th has remained a about 36, pulse varying from 84 to 120, and T. from normal to 101° F.

Physical examination of the chest soon after the sudden accession of acute symptoms determined the presence of fluid in the right pleural cavity, and the succussion sound settled the question that the cavity also contained air. The case, therefore, was not one of simple pleurisy, but was first one of pneumo-thorax, which quickly developed into pneumo-hydrothorax.

The case afforded an excellent illustration of the possibility of determining by percussion the condition which had given rise to the flatness or extremely marked dulness present upon the right side. It was

not due to edema of the lung, for that is almost always *double*; tumors could be safely excluded, for they are very rare in this region; and lung solidification was thrown out of the estimate because the level of resonance could be most markedly changed by changing the position of the patient.

There was another point of some interest in the examination, and that was, the case illustrated very well the difficulty of determining by percussion alone whether there was simply a pleuritic effusion present, or whether the liquid was accompanied by air in the pleural cavity. The resonance was more intense, differed in pitch, and had more of the tympanitic quality above the level of the fluid than over the lung tissue upon the opposite side, but it was scarcely more intense or changed in pitch and quality than might be expected over a lung which is crowded up by a simple pleuritic effusion, and thus showed the necessity of further examination. Happily in this case the percussion sound was very well marked, which determined the diagnosis at once.

The case also suggested some questions relative to treatment. The indications, so far as relief of present symptoms was concerned, were negative, for the patient was lying comfortably upon the bed, and could assume the sitting posture without much difficulty of respiration being produced. But in view of the termination of a vast majority of these cases, the question arose, Would it be justifiable to at once remove the fluid from the pleural cavity? In those cases in which the effusion is large, and is the immediate cause of dyspnoea, which demands relief or threatens fatal syncope, etc., puncture, it seems well established, is justifiable and demanded. But in a case like this, now quite comfortable, is a free opening into the pleural cavity, by making an incision through the chest-walls, justifiable?

The question, it was urged, has not yet been satisfactorily answered by clinical experience. There was an inclination, however, to the opinion that the operation is proper in such cases. An important item in this particular instance, bearing upon the line of treatment to be followed, was the fact that the patient had renal disease, as evidenced by the urine having a uniformly low specific gravity (1.012), and containing hyaline and granular casts, although *no* albumen had been detected. The case, therefore, illustrated the necessity of making further examination of the urine for the detection of renal disease than merely testing it for albumen.

GNORRHEA—EPIDIDYMITIS.

This case was interesting in several particulars. A patient, æ 24, who felt perfectly well on Thursday morning, received a slight injury of the right testicle in the afternoon, and was awakened the same night by pain in the organs, although it was not very severe. In the morning he noticed that the testicle was somewhat swollen and red, but he continued to work, and in the course of the day it got hurt again. He continued at his work (expressman) three days, and then sought admission to the hospital. When admitted his temperature was 105° F., R. 30, P. 110, and the surface of his body bathed with perspiration. The testicle was found swollen, tender, and red, but not excessively so, and extremely painful. There was one noticeable feature of the case, namely, the severe constitutional disturbance following a slight injury of one of these organs.

Four leeches were applied upon the scrotum, and followed by a hop poultice. Morphine and aconite were administered to relieve pain and lower the tem-

perature. Two days after admission, when the constitutional disturbance had subsided to a very great extent, a slight purulent discharge made its appearance at the meatus. Was it gonorrhoeal or was it the result of the injury? It has been claimed by some writers that injury to the testicle may be followed by purulent discharge from the meatus, and in this case there was a history of injury and no acknowledgment of the existence of any discharge *prior* to receiving the injury. The man, however, admitted that his urine had for several days before the injury caused a slightly smarting sensation when voided. The diagnosis was epididymitis following gonorrhoea.

The treatment was criticised in the following particulars: The leeches would have been more effectual had they been applied along the course of the spermatic cord, which is directly over the seat of the most intense pain. Another reason for applying them over the cord, and not over the scrotum, is, that there is less liability of extravasation of blood taking place into the cellular tissue, and developing subsequent serious trouble in the way of ecchymosis, and perhaps erysipelas. Such accidents occasionally happen. Again, it was the opinion of the surgeon in attendance that the intense pain attending an attack of epididymitis is really due to the formation of an acute hydrocele, and that this can be much more readily relieved by introducing a small needle and removing the fluid than by the administration of opium, for by so doing the pressure is at once removed from the inflamed organ. Sometimes that will not answer, and then leeches and other measures must be resorted to. A very convenient suspensory bandage was in use in this case, the patient being in bed, and consisted of a broad strip of adhesive plaster, one extremity of which was attached to the anterior surface of one thigh, while the remaining portion was stretched underneath the scrotum, and secured to the anterior surface of the opposite thigh. In this manner the whole thing, as it were, was laid upon a shelf for repairs. Wearing a suspensory bandage was mentioned as a very important item in *preventing* the occurrence of epididymitis during the progress of a gonorrhoea.

TYPHOID FEVER—HIGH TEMPERATURE TREATED WITH SULPHATE OF QUININE AND HOT PACK.

There were three cases of this affection which presented some points of interest common to all of them.

First, The patients were young persons, aged 21, 16, and 21, respectively.

Second, The forming period of the disease was unusually *short*. In one case the patient was in bed the second day after first feeling ill; in the *second* case he felt chilly in the morning, worked in the afternoon, but was unable to get up the next morning; while in the *third* case the patient went to bed the second day after he began to feel "dull and lazy."

Third, The eruption was well marked, but not abundant.

Fourth, There was only slight abdominal distention, and diarrhoea was present in only one case, and that only in a mild form. There had been epistaxis in one case, and all three had a moderate amount of tenderness in the right iliac region.

The special point of interest, however, in these cases, related to the temperature of the patient and the manner in which it was treated. The record of each case will be given separately.

The first patient was admitted Sept. 2.

Sept. 3. His P. was 84, R. 24, T. 100° F. morning, and in the evening $103\frac{1}{2}^{\circ}$ F., when he received ten grains of sulphate of quinine. On the morning of Sept. 4 his T. was $101\frac{1}{4}^{\circ}$ F., and in the evening $103\frac{1}{2}^{\circ}$ F.

The patient then received twenty grains of the sulphate of quinine, and on the morning of Sept. 5 the T. was 101° F., and the pulse 66. This apparently was an effect produced by the quinine. At 6 P.M. his T. was at 104° F., and ten grains of quinine were administered. At 7 P.M. his T. was 104° F., and ten grains more were given. At 8 P.M. his T. was 103½° F., and the patient received ten grains more; and at 9 P.M. his T. was 102½° F., and ten grains more were administered. In this instance it was believed that the reduction of the temperature was clearly due to the effect of the quinine, because at that hour we should naturally expect the T. to be as high as at any time during the day.

The next morning the temperature was 100½° F. At 2 P.M. fifteen grains of quinine were given, and at 3 P.M. the temperature was up to 103° F. At 6 P.M. T. 104° F. At 7 P.M. T. 104° F., and now twenty grains of quinine were administered. At 10 P.M. his T. was 100½° F.

Here again the reduction in temperature may fairly be regarded as due to the effect of the quinine.

On the day following, however, the temperature again arose, and when at 102° F. ten grains of quinine were given, and repeated every hour without producing any effect, while the thermometer arose to 103° F., and finally reached 104° F.

It might be said that the temperature would have risen higher had not the quinine been administered, but certain it was that it steadily arose while the drug was being exhibited. From this date, the 8th of September, his temperature ranged from 101° F. to 104° F., and in the afternoon of the 11th it reached 104½° F. when twenty grains of quinine were given, and a sheet wrung out of *hot water* was wrapped around the patient. In the meantime he had received ten grains of quinine every four or six hours upon an average, and when at any time the temperature arose to 104° F. twenty grains were given. The temperature fell only ½° F. after applying the hot pack. On the 12th the T. reached 105° F.; the hot pack was again resorted to, and it fell ½° F. within fifteen minutes.

On Sept. 17, 1.30 P.M., his T. was 104½° F., and then the cold pack was resorted to. In this case the high temperature was the only grave feature, but that was held in abeyance by means of the cold pack.

The second case was admitted Sept. 4, with a T. of 105° F., which soon fell to 104° F., when twenty grains of quinine were administered and the stomach rejected it. Two hours afterwards the temperature had fallen 1° F. without treatment. On the 6th of Sept., at 6 A.M., his T. was 103° F., and ten grains of quinine were given. At 9 A.M. his T. was 103½° F., and at 10 A.M. he was packed in the hot wet sheet, and the temperature was reduced to 101½° F. At 2 P.M. his T. was 103½° F., and he now received ten grains of quinine each hour for two hours, and at 4 P.M. the temperature was 102½° F., while at 9 P.M. his T. was 103° F. Sept. 7, 6 A.M., T. 102° F.; 8 A.M. T. 101½° F., ten grains of quinine were then administered. At 10.30 A.M. his T. was 104° F., and ten grains more of quinine were given. At 12 M. his T. was 103½° F., and at 1.20 P.M. the thermometer stood at 104° F. At 2 P.M. the *cold* pack was resorted to, and at 2.30 P.M. his T. was 101½° F. At 4.15 P.M. the temperature had risen to 103½° F., and the cold pack was repeated. This patient had been treated in about this manner, so far as temperature is concerned, receiving from twenty to forty grains of sulphate of quinine daily, and cold packs latterly as occasion seemed to demand. The action of the quinine has not been marked in any direction. The temperature has become high while it was steadily ad-

ministered, and it has also fallen to some extent. It is now eleven days since the admission of the patient, and he is doing very well.

The third case was admitted Sept. 13, and was at once placed upon quinine, five grains three times a day. On Sept. 14 his evening temperature was 104° F. Sept. 15, morning, T. 102½° F., evening, T. 103° F.

The hot pack was at once resorted to, but *no* reduction of temperature was produced. Sept. 16, morning T. 101½° F., evening T. 103½° F.

The hot pack was again resorted to, but *without* effect. Sept. 17, T. 104° F., and the *cold* pack was ordered at once.

GASTRIC ULCER—MILK TREATMENT.

A female patient suffering with this disease was admitted, and at once placed upon such quantities of milk as could be taken without being rejected by the stomach. The amount given at first was only a teaspoonful, which could be repeated about every twenty minutes. The milk was increased in quantity only as it could be tolerated by the stomach, and the patient was then able to take half a glass at a time. In addition, a piece of cardboard about the size of a five-cent nickel was dipped in nitric acid and laid over the region of tenderness in the epigastrium, and permitted to remain until the cuticle was destroyed, when it was removed and the sore kept open by dressing it with a piece of adhesive plaster. This patient had been in the hospital several times suffering from the vomiting, etc., incident to this affection, and had usually been treated with injections. But her recovery at this visit had been equally prompt and much more agreeable, although her symptoms had been as severe as at any previous admission.

SCIRRHUS OF THE FEMALE BREAST.

This case presented a few points of more than ordinary interest. In the first place the family history of the patient was good, all her near relatives having been healthy. In the next place she had always enjoyed excellent health until two years ago, when she was seventy-three years of age. She then discovered a lump in the left breast about the size of a walnut, but could not assign any reason for its appearance, such as a blow or other injury. Soon after the breast was removed, the wound healed kindly, and the patient had no further trouble, until about one year ago, when she discovered a lump in the *remaining* breast, which was of about the same size of the one that appeared in the left breast, and it gave her the same characteristic lancinating pains as did the first tumor. The second tumor has increased in size rather rapidly, and now involves the entire gland; is moderately adherent to the tissues underlying it. Ulcerative action has just commenced, and to some extent the disease has involved the surrounding skin; but the gland, in the axilla of the *same* side remain unaffected, while one upon the *opposite* side is nearly two inches in diameter, and is growing. It is also extremely sensitive to the touch, is somewhat painful, and yet has been observed only two weeks. Cases of this kind are quite rare, and the chief interest centres upon the recurrence of scirrhus disease in the opposite breast, involving the gland to such an extent as seen here without affecting the axillary glands upon the same side, but with coexisting manifestation of the disease in axillary glands of the left side, where the primary tumor was developed. Another point of interest was the absence of retraction of the nipple, where the disease was so far advanced as in this case. The old cicatrix was movable, and presented a perfectly

healthy appearance. The patient was comparatively comfortable; the pain was not sufficient to prevent sleep, and is not severe at any time. In consideration of her age, present condition, the mass more or less adherent, the integument more or less involved, and manifestation of the disease in the opposite axilla, operative interference was regarded as contra-indicated. Still, if the patient desired its removal, if it was torturing her with pain, or if it was a source of mental annoyance, an operation was regarded as justifiable. In the event of an operation it would be necessary to receive both masses of the disease.

DYSURIA.

The following prescription is a very valuable one for the relief of dysuria, especially in women, accompanied with a scalding sensation, voiding only small quantities of high-colored urine, etc.:

℞ Ext. belladonnæ fld. ʒ i.
Ext. buchu fld. ʒ i.
Spts. ætheris nitrat. ʒ ij.
M.

S. Teaspoonful four times a day.

If the eyesight is much affected the quantity of belladonna may be diminished.

ASTHMATIC MIXTURE.

The following will relieve the attacks of asthma in a goodly number of cases:

℞ Potass. iodid. ʒ i.
Vin. ipecac. ʒ ij.
Spts. ether. co. ʒ i.
Syr. simplicis. ʒ i.
Aquæ. ʒ v.
M.

S. Teaspoonful every two hours during paroxysm.

ANTI-BILIOUS PILL.

℞ Pil. hydrarg.,
Pulv. aloes soc.,
Pulv. rhei,
Ext. hyoseyami. ʒ ʒs. vi.
M.

Div. pil. No. vi.

S. Two every other night.

The above will be found to be a most excellent pill for the relief of many dyspeptic symptoms, such as nausea, constipation, vertigo, etc., and can be followed with advantage by a pill made according to the annexed formula:

PILL FOR DYSPEPSIA.

℞ Ext. nucis vom. grs. v.
Pulv. rhei,
Sodæ bicarb. ʒ i.
M.

Div. pil. No. xx.

S. One three times a day.

EVAPORATING LOTION TO PREVENT EXTENSIVE ECCHY-
MOSIS, SUCH AS FOLLOWS BLOWS, ETC.

℞ Ammonie muriat. ʒ i.
Alcohol ʒ iv.
Aquæ. Oi.
M.

Apply cold, and keep the parts constantly wet.

ANTI-PRURITIC REMEDY.

℞ Gum camphor,
Chloral hydrate. ʒ ʒs. i.
Rose ointment. ʒ i.
M.

The rose ointment is preferred because it does not get rancid. This application does not answer when the skin is scarcely broken.

FOR CEREBRAL CONGESTION.

℞ Sodæ bromid. ʒ i.
Oxid. zinc. ʒ i.
Sacch. pepsin. ʒ ij.
Hydrochloro-phosphat. calcis,
Ext. ergot fld. ʒ ʒs. ij.
M.

To be administered in drachm doses. The hydrochloro-phosphate of lime is made by saturating dilute hydrochloric acid with phosphate of lime.

* COUGH MIXTURE.

Opium does not enter into this prescription, and it can, therefore, be used with special advantage in the treatment of the cough of consumption:

℞ Acid. hydrocyanic. dil.,
Chloroform. ʒ ʒs. i.
Tr. hyoseyami. ʒ ʒs. ss.
Aq. camph. ad ʒ ij.
M.

S. Teaspoonful in a wine glass of water three or four times a day.

FOR SPERMATORRHEA.

The following will be found serviceable in the treatment of this difficulty:

℞ Potass. bromid. ʒ i.
Tr. ferri. chlorid. ʒ i.
Aquæ. ʒ ij.
M.

S. Two teaspoonfuls three times a day.

The taste of the dose is disgusting, but the effects are excellent.

The following has a popular hospital reputation as a

POST-PARTUM PILL.

℞ Ext. colocynth eo.,
Hydrarg. submuriat. ʒ ʒs. ij.
Ext. nucis vom.,
Pulv. aloes,
Pulv. ipecac. ʒ ʒs. xx.
M.

Div. pil. No. 120.

One to four to be taken at a dose, and instead of castor-oil after parturition.

The following is a popular

LAXATIVE,

and a most admirable combination. It is particularly serviceable in the treatment of dyspepsia:

℞ Sodæ bicarb. ʒ i.
Pulv. rhei. ʒ ij. to ʒ ss.
Tr. menth. pip. ʒ ij.
Aquæ. ad ʒ iv.
M.

Dose, tablespoonful. Shake the bottle before taking, and repeat according to the effect upon the bowels.

FOR MUSCULAR RHEUMATISM.

℞ Ammon. muriat. ʒ i.
Tr. ferri. chlorid. ʒ i.
Aquæ. ʒ ij.

S. Two teaspoonfuls t. i. d.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

SANITARY REFORMS IN OUR SCHOOLS.

THE interest which is manifested in the sanitary care of school children is every little while freshened by some suggestions in the shape of resolutions from scientific bodies. At the recent meeting of the British Medical Association attention was directed to the subject by the Section on Public Medicine. In the report which it presented the defects of the general school system were graphically described, and many very sensible remedies suggested which it is worth the while of our School Commissioners to take into account. It seems strange, indeed, that facts which are so palpable to every superficial observer should require such constant reiteration in order to establish conviction and bring about reforms which ordinary common sense should at once conclude were necessary. For the very reason, perhaps, that remedies are so easy and the truths so plain, no energetic initiations are taken by our practical educators. No one is willing to doubt the fact that it is highly important for the young scholars to have healthy surroundings; that they should be properly guarded against the effects of constant violation of sanitary laws; yet our schools continue to be over-crowded, our buildings are defective in facilities for heat, light, and ventilation, and contagious diseases spread with a certainty which it is fearful to contemplate. This has been proven over and over again within the past few years, leaving no room for the reasonableness of the appeals of those of us who, perhaps vainly, wish for better things. There is no need for attempting to establish these premises in the attempt to carry out the argument for school reform, as they are not only self-evident, but are freely admitted to be sound by all who are directly or indirectly interested in the question at issue.

The suggestions of the Section on Public Medicine referred to, although not exactly new as to the results sought for, carry with them a novelty as to the means to be employed which may be made practicable with

us, and which may tend to correct many crying abuses connected with the construction of our various school buildings, both public and private. It is proposed that no buildings be allowed to be used as schools unless certified by a surveyor and medical officer of health as in every respect adapted to educational purposes; that the maximum number of children to be admitted to each school be fixed, and that the medical officer of health have access to the premises for purposes of inspection at all reasonable hours.

If these provisions could be faithfully carried out, it can be easily seen that much good would be accomplished. In order that such could be done, however, by our School Commissioners, some changes in the organization of the present system might be called for. The necessity of medical inspection forces itself upon their consideration at the very outset, and may touch them upon a question of conscience which they have attempted to ignore by a foolhardy opposition to the arguments of the entire medical profession. We care not how the case may be viewed, proper sanitary inspection lies at the very foundation of all hope of any change for the better. It matters not how the details of such an inspection may be carried out, or to whom the duties may be entrusted, whether to one or many, whether to an officer appointed by the Board of Commissioners of Education or a member appointed by the Health Board, the good results would be, practically speaking, the same. The arguments in favor of establishing the principle of sanitary inspection have been long ago worn threadbare, and a restatement of them is at this time obviously unnecessary.

The recommendations regarding sanitary inspection have an equal application to the various private schools throughout the country, which seem to be entirely independent of any outside influence or authority. Many of these institutions are excellently managed, and may, in a hygienic sense, be considered models of their sort, but this is by no means true of the majority. How often are children crowded together into a small apartment of some private house, in which no other provisions for sanitary requirements are made than are sufficient for an ordinary family. The air capacity of such so-called school-rooms is never taken into account, the main desideratum being to occupy all the available floor space by desks and benches. The Health Board is competent to act under these circumstances, and exercise a very needful authoritative control over these pecuniarily ambitious pedagogues.

But, as we have said before, we are more interested as to the necessity of such inspection than to the manner in which the details of any system may be carried out.

HOSPITAL STEWARDS OF THE ARMY.

THE complaints of our correspondent—one of the hospital stewards of the army, who speaks in behalf of his corps—are reasonable and just, but we fear that the remedy sought is a long way off. Still there is nothing

like agitating any question tending towards the reform of abuses.

The unsuccessful struggles by the medical staff, for this very increase in rank and pay, shows what the stewards have to hope for. We would not advise them to take any active steps towards maintaining their rights until the question is settled with the medical staff. Then the proper foundation will, in our opinion, be laid for the effective working of those influences which are so necessary to secure the end in view.

Reviews and Notices of Books.

TRANSACTIONS OF THE MEDICAL ASSOCIATION OF THE STATE OF ALABAMA. 28th Session, 1875, at Montgomery, April 13th, 14th, and 15th. Montgomery, 1875.

THIS is a paper-bound book of 360 pages, and contains, besides a condensed report of the Transactions of the Society and the "House of Councillors," the second annual report of the Board of Censors relative to the new law constituting the Society the Health Board of the State. The President's address and an annual oration by Geo. A. Ketchum, M.D., of Mobile, are printed in full, together with the following elaborate papers:—Tuberculosis and Scrofulosis, by E. P. Gaines, M.D., of Mobile; Climate of the United States, considered with Reference to Consumption and Pneumonia, by W. D. Bizzell, M.D., of Mobile; Malaria, its Nature and Mode of Spread, by Benj. H. Riggs, M.D., of Sedalia; Recent Progress in Gynecology, by F. M. Peterson, M.D.; History of the Small-pox Epidemic in Mobile, 1874-75, by Jerome Cochran, M.D., and The Health Ordinance of the City of Mobile. Several smaller papers are distributed through the volume, among which is one by James Guild, M.D., on a Case of Lithotomy, and another of Wound of the Brain, the latter of which is so unique that we quote it entire.

"Col. D. H. B., in an affray with a distinguished member of Congress, received a wound on the occipital bone with a spear from his sword-cane. Soon after, he was attacked with epilepsy, which continued to increase in intensity for two years, notwithstanding all the medical aid that could be instituted was applied. It so happened that the combatants, some two years after the affray, met in Tuscaloosa, made friends, and retired to a saloon to take a social glass together. Excuse me for relating the incident as it occurred.

"Before or about taking their beverage, the Congressman observed, 'Col. (with an oath), there is a piece of my sword-cane in your brains.' The Col. asked for an explanation. He was informed that 'after the fight, I discovered that the point of my sword-cane was broken off; and to a certainty it is in your brains.'

"The Colonel, without taking his glass of liquor, made haste to my office, and related to me what had just occurred. It struck me immediately it was all true, and that it was the cause of the fits. On making an examination, I found a slight protuberance on the occipital bone, which he informed me occasionally issued a little matter.

I immediately shaved off the hair, made a transverse incision, exposed the bone, and found the spear broken off even with the skull. I thought of trepanning over

the spear in order to liberate it, but procured a common hand-saw file, and filed away the skull on each side of the spear so that I could get hold of it with the forceps. Accordingly, I used a pair of tooth-forceps and succeeded in extracting the spear, which, by measurement, entered the brain about one inch. It was the last of his convulsions."

The book is notable as an example of good printing and editorial taste, aside from the value of the papers it contains.

THE MUCOUS MEMBRANE OF THE UTERUS, with Special Reference to the Development and Structure of the Decidua. By GEO. T. ENGELMANN, A.M., M.D. New York: William Wood & Co., 27 Great Jones Street.

THIS little monograph, which is a reprint from the May number of *The American Journal of Obstetrics*, gives us in some sixty-odd pages a concise record of histological work, most of which was done in Vienna and Berlin, and in great part with the co-operation of Dr. Kundrat, of Vienna. The main conclusions were published in *Stricker's Medicinische Jahrbücher* for 1873, but the subject has undergone revision since that time, and so many alterations and additions have been made that the present publication is in many respects new. The subject-matter is prefaced by an elaborate and minute description of the changes that take place in the uterine mucous membrane from foetal life until the period of uterine inactivity. A noteworthy point is the denial of Pouchet's theory, lately revived by Williams, that the mucous membrane is shed at each menstrual epoch; the author states that he has studied the membrane immediately after the flow had ceased, and has never found the epithelial coating entirely absent, though a portion of its upper layers is sometimes expelled, as in membranous dysmenorrhœa. At the menstrual periods the cellular elements of the mucous membrane undergo a sort of fatty degeneration, and this change he holds to be the cause rather than the consequence of the hemorrhage. The description given of the surface of the uterus after parturition is interesting, and may be more available for practical purposes, as indicating the nature of the tract through which the poison in puerperal fevers finds entrance into the system. The author denies emphatically Cruveilhier's statement, that the uterus, after delivery, is laid bare down to the muscle, as also the view that a new mucous membrane is formed during pregnancy.

When parturition takes place at full term the ovum carries away with it the whole of the decidua reflexa, the entire upper cellular layers of the decidua serotina—that portion of the decidua lying between the uterus and the ovum—with its uppermost epithelial layer, while the greater portion of the decidua vera, and the spongy lower portion of the serotina vera remain attached to the uterus. This, then, explains how the epithelium can again be reproduced, for, as Friedländer has shown, the portion of the decidua now remaining behind is dotted with minute depressions, which are really the uterine follicles, clothed with epithelium, and from them, as centres, the epithelium covering is again to be formed, the cell-layer partly covering them, and the thickened connective tissue about them, together with the thrombosed vessels, all gradually disappearing by absorption. We are not justified in going into further details, though we may mention that the author's investigations showed that ovulation and menstruation are coincident in point of time, being thus in agreement with Dalton and Coste.

The monograph bears the impress of a large amount

of careful and methodical scientific work, and it will, doubtless, be regarded as a valuable contribution to our anatomy. The style is clear and forcible, and there are excellent cuts to show the appearances that were observed.

Progress of Medical Science.

THE EFFECTS OF LEAD UPON TYPE-FOUNDERS AND PRINTERS, AS OBSERVED IN LEIPSIK.—In Leipsic, states Dr. Stumpf, are thirteen large type-foundries and seventy-two book-printing establishments, and he therefore regards it as a particularly favorable place to study the diseases to which those persons are subject whose business requires them to be constantly handling the type. The type-metal is an alloy of lead and antimony, to which small proportions of tin and copper are sometimes added. He describes the processes through which the type has to go, in the course of manufacture and finishing, and finds that of all the workmen engaged on this work the founder is most exposed to danger from the volatilization of the heated metal. Coming to the type-setting, he finds that here the right hand is most employed, and yet the nature of the work brings the face of the type-setter so near that he is in danger of swallowing or inhaling small particles of the metal. In printing it is only in the use of hand-presses that the workmen are much exposed. Here the hardest work falls upon the right hand, and on the principle that those muscles which are most used would furnish the greatest amount of tissue change, and so would retain most lead from increased access of blood, he explains the fact of the right hand being most commonly affected by lead poisoning among this class of workmen. Dr. Stumpf then collected specimens of the dust found in different parts of the establishments, and at different heights in the rooms, and on chemical and microscopic examination the metallic elements were found in all the specimens, thus proving the air constantly breathed by the workmen to be impregnated with such particles. Of course the quantity of such impurities varies greatly. In winter, *e.g.*, when the windows are closed, and there are fewer currents of fresh air, the proportion is greater, and the statistics show a greater poisonous influence at this season. Of course there are various other ways besides inhalation by which the metallic particles are introduced into the system.

Dr. Stumpf's investigations would indicate that in printers and type-founders the lead does not enter the system through the epidermis; the mucous membranes, however, furnish a readier means of entrance, as evidenced by the frequency of affections of the respiratory and digestive organs due to lead-poisoning.

In the liver especially is lead to be found, and next in frequency in the muscles. The extensor muscles of the right hand are the most frequently affected. Lead is also found in the kidneys, blood, bones, and lungs, but only the merest traces in the nervous system. The author believes that the deposit of lead stated to take place in the smooth muscular fibres of the blood-vessels, by diminishing their calibre helps to explain the atrophy of the muscles, and also the occurrence of abortion. Many of the facts which we have thus extracted from Dr. Stumpf's paper, and many others for which we have not room, are supported by a series of statistical tables which he has constructed from the

material furnished at the Polyclinic in Leipsic, during a series of four years.—*Archiv der Heilkunde*, Aug. 9, 1875.

THREATENING COLLAPSE AFTER THE ADMINISTRATION OF APOMORPHIA.—The dose of apomorphia as an emetic for an adult appears to be about $\frac{1}{16}$ grain, though $\frac{3}{16}$ has been used without harm. Several authors, however, have counselled greater caution, and the following case, reported by Dr. Prevost, of Geneva, shows the need of it. To a lady of forty, at an early stage of an attack of bilateral angina tonsillaris, was given at 9.45 o'clock a hypodermic injection containing not above $\frac{1}{5}$ grain of muriate of apomorphia. In four minutes she became nauseated and dizzy, and very soon after pale and collapsed; the pulse grew weak, intermittent, and finally imperceptible; the pupils became dilated, and respiration seemed to have stopped. She was unconscious also. She was placed with the head low, was sprinkled with cold water, the skin rubbed, and sinapisms applied to the calves. After three minutes she revived so far that the pulse could be felt, and she vomited twice. She now regained consciousness, and spoke, but almost immediately sank into a more profound faint than before. Under similar treatment she revived by 10.25, so as to speak again, and her pulse beat 88 to the minute. She vomited again without fainting, was given brandy, and soon fell asleep. By noon the next day she had quite recovered.—*Gaz. hebdom.*, 2 Sér., xii., 2, p. 20, 1875.—*Schmidt's Jahrb.*, Aug. 12, 1875.

A PECULIAR FORM OF PURPURA.—Prof. Hensch gives the histories of four cases, all occurring in persons of fifteen years or younger, in which there were associated the following unusual group of symptoms, *viz.*, rheumatic pains in the joints, the development of purpuric spots, intestinal colic and bloody discharges from the bowels, with some fever. These affections were subject to relapses after they were apparently recovered from, and thus lasted through a period of weeks, in one case three months. The rheumatoid symptoms always preceded the separate attacks. The purpura was most marked upon the abdomen, the genitals, and the lower extremities, and was not seen on the face. The author has been able to find reports of but three similar cases. In one reported by Wagner (*Arch. d. Heilk.*, x., 4, p. 361, 1869), in addition to the symptoms described by Hensch, there were albuminuria and membranous shreds in the alvine evacuations. This patient died, and the autopsy revealed purulent peritonitis and a highly developed enteritis, with numerous superficial ulcerations of the mucous membrane, follicular swelling, and in places deposits of false membrane. Hensch believes that these various symptoms have some intimate relation with one another, the nature of which is yet to be explained.—*Berl. klin. Woch.*, xi., 51, 1874.—*Schmidt's Jahrb.*, Aug. 12, 1875.

AFTER-HISTORY OF FIFTY-ONE CASES OF LITHOTRITY.—Sir Henry Thompson gives the record of recent cases at from one and two years after the operation, in reply to a request of Mr. Thomas Smith, who desired to know the condition of the patients at any period not less than twelve months after the procedure.

In this series fully twelve months have passed since the date of the last operation, and more than two years and a quarter have elapsed since the first of the series was operated upon.

Between December, 1872, and May, 1874, Sir Henry has performed lithotritry on 53 patients, two of whom

died, leaving 51 cases of recovery, the mean interval between the date of operation and the present report of their condition being about twenty months.

From 6 of the 51 no information has been received, but he believes that such evidence as exists in regard to them is greatly in favor of their being better, and not worse, than the average, since their mean age is fifty-four years, nearly ten less than the average age of the whole series.

Of the remaining 45, 11 have since died, the causes of which were, organic heart disease, 2; malignant disease, 1; of natural decay, at eighty, 1; the remaining 6 of urinary disorders and advanced age together (the mean being sixty-six years). Five of these six had not passed any urine, except with the aid of the catheter, for years past, and their prolongation of life had been entirely due to the improved modern means of removing retained urine and phosphatic deposits.

Of the 34 living, 28 are enjoying good health, at an average age of sixty-three and a half years.

The other 6 have signs of recurring calculus, 2 having had a newly formed calculus removed.

All are well but one of these, who suffers much.

The comparative mortality between lithotomy and lithotripsy, taking into account their average age, sixty-three years, is considered, and it is stated that 14 deaths in lithotomy would not be thought a bad result in such cases.

A detailed account of the 51 cases concludes the article.—*The Lancet*, July 3, 1875.

THE TREATMENT OF DIARRHŒA IN CHILDREN.—In a recent (July 8) number of the *Boston Med. and Surg. Journal*, Dr. J. P. Oliver presents some practical hints concerning the treatment of that common form of diarrhœa in children which depends upon the non-digestion of the food. The disease is most apt to attack children between the ages of six months and two years, and during the hot season of the year. The attack is often excited by taking some indigestible article of food, or after an exposure to cold a diarrhœa is produced, which tends to become chronic. The stools are acid, and consist of a peculiar, light-colored, pasty-looking substance, mingled with mucus, and perhaps streaked with blood. Progressive emaciation and debility ensue, and, finally, a fatal termination either in connection with cerebral symptoms or as a result of some intercurrent affection. The main points in Dr. Oliver's treatment of this form of diarrhœa appear to have reference to deficiency in the catalytic force displayed in the process of digestion and to the excessive acidification with which the digestion is associated. When undigested food is found in the dejections, it is inferred that the child's diet is not adapted to its digestive powers. If the diet has consisted of pure milk, the addition of gelatine to the milk, as recommended by Meigs and Wyman, will often assist digestion indirectly by preventing coagulation in the stomach, and thus enabling the "digestive agents" to operate at a greater advantage. As a rule, a farinaceous diet is unsuited to infancy, on account of the inability at this early period of life to effect the transformation of starch into sugar. In the so-called Liebig's soup, however, the presence of diastase in the malt supplies the defective ferment in the stomach, and assists to digest the flour which the soup contains. Sometimes this preparation, therefore, is well borne in quite young children. Its effect must be tested by inspection of the stools. For children who can be supplied with cream or good milk, no other food is thought necessary. The excessive acidification is best combated, according to Dr. Oliver, by means of the

bicarbonate of potassa, to which the addition of an aromatic is advised. The potash is preferred from the fact of its being a natural constituent of the milk. When the powers of life begin to fail, and but a small quantity of food can be taken at a time, beef-tea is given, to which a little saccharated pepsin is added. If the fontanelle becomes much depressed, stimulants are indicated.

THE CAUSES OF THE SPONTANEOUS COAGULATION OF THE BLOOD AFTER ITS ESCAPE FROM THE BODY.

—According to F. Glénard, when a certain length of an artery or vein full of blood in a living animal is isolated and exposed to the air, the blood does not coagulate, whatever be the capacity of the vessel. After a variable time, depending upon the volume of the vessel and the amount of blood contained in it, the blood becomes so dried as to present the consistency of horn. If, while in this state, the blood is made into a serous or pulverulent mass, and is then treated with water, it dissolves, and this solution is susceptible of coagulating spontaneously in a mass, even after filtration.

The prevention of the coagulation is directly owing to the concentration of the blood; if in the previous experiment evaporation is prevented, the blood coagulates spontaneously, but not before the expiration of from twelve to fifteen hours after its isolation from the animal, and not in five or ten minutes, as is the case when it is received into a basin.

In venesection the coagulation of the blood in the basin is due to the contact with a foreign body.

In fact, the only instance in which the blood is seen after its escape from the system to preserve a fluid condition for as much as twelve hours, without the intervention of artificial, physical, or chemical agents (such as cold or alkaline solutions), is where the contact with foreign bodies is prevented.

The influence of foreign bodies upon coagulation is less in proportion as these bodies resemble the vessels in their physical structure.

Aside from the contact of foreign bodies, not one of the new conditions by which the blood is encompassed on issuing from the system is capable, either by itself or in combination with the rest, of determining coagulation. Coagulation is not normally due to any gaseous intervention of a chemical nature, either in excess or through deficiency.

The blood that is enclosed in the vessel thus isolated from the animal may be impregnated with carbonic acid, oxygen, even with hydrosulphuric acid, without coagulating and without losing its coagulability, as evinced when it is received in a basin (foreign body).

Blood preserved in the vessels is capable of being revived by being rendered fluid, and beef's blood, seven hours after issuing from the organism may be successfully employed for transfusion in a dog bled nearly to death.

The blood is living to the extent that it is spontaneously coagulable. Coagulation is the death of the blood. The coagulability is suspended, but not destroyed, by concentration of the blood, just as the manifestations of life are suspended in the rotifers by desiccation; in both cases the addition of water restores the physico-chemical conditions necessary in the one case to perform the functions of life, in the other to coagulate spontaneously.—*La Tribune Medicale*, August 15, 1875.

PROFESSOR MASCHKA, of Prag, is to occupy the chair of medical jurisprudence in the University of Vienna.

Correspondence.

TREATMENT OF EPIDEMIC DISEASES
DURING THEIR INCUBATIVE STAGE
BY THE USE OF THE THERMOMETER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Reflecting upon diseases and their causes, we naturally inquire why it is that in the same house, during an endemic or epidemic, where the different individuals are surrounded by the same hygienic influences, and inherit the same constitutional tendencies, they are differently affected by the same disease—one having a light attack, another case proving fatal, and the others suffering from attacks of intermediate severity?

The differences in the type of diseases under these circumstances is caused by the functional disorders which result from the individual habits. These reflections in giving us the causes also indicate the remedy, viz.: That during the prevalence of epidemic and endemic diseases we should carry our hygienic measures a little farther, and not only remove and destroy the causes which exist without the body, but also those (which I consider of greater importance) from within the body—the disordered secretions.

If we pursue this plan strictly, we reduce the attacks to their minimum severity, and prevent a great many, who would otherwise have been infected, from taking the disease at all. The number of lives which can be saved by this method has been proved by the practice of inoculation in small-pox.

In addition to the above measures we can take another step, which, if carried out with equal strictness, will, I believe, enable us to “STAMP OUT EPIDEMICS.”

I PROPOSE TO TREAT THESE DISEASES DURING THEIR INCUBATIVE STAGE. BY THIS METHOD WE WILL ALMOST INVARIABLY PREVENT THEIR FURTHER DEVELOPMENT, AND INSURE A UNIFORM SUCCESS IN THEIR TREATMENT.

This plan is rendered practicable by the use of the “THERMOMETER.” We can place a thermometer in the hands of a member of each household, having instructed them in its use. This person can take the temperature of each individual in the house three or four times during the twenty-four hours—say at 6 A.M., 12 M., 6 P.M., and at 10 or 12 P.M. Upon discovering the slightest deviation from a normal temperature immediately notify the physician.

For the pauper districts instruct members of the Benevolent and Christian Associations in the use of the thermometer, and assign to each one so instructed two or more houses.

A printed circular containing explicit directions for the proper observance of hygienic rules, and impressing the importance of their strict application, should be placed in every house.

During the prevalence of an epidemic a physician should be appointed to enforce these regulations.

In the hospitals, military and civil, this system could be carried out with facility, and its usefulness demonstrated.

BENJ. S. PURSE, M.D.

SAVANNAH, GA.

ELECTRICITY IN VOMITING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Among numerous letters corroborating my statements regarding the efficacy of electricity in vomiting, from whatever cause, received by me since the publication of my paper in the second number of the *Archives of Electrology and Neurology*, I select the following for publication, as of more than usual interest, especially as it comes from a foreign source. It is reported to me very briefly, not for publication of course, by Dr. James Cecil Phillippo, of Spanish Town and Kingston, Jamaica, a physician in large practice there.

Respectfully yours,

FREDERIC D. LENTE, M.D.

“CASE.—Shortly before leaving Jamaica, and after having read your paper on the use of electricity in vomiting, I had a very interesting case of vomiting in pregnancy, which no known drug could even alleviate. She had suffered similarly on previous occasions for months; but on this occasion it bade fair to be worse than usual. She was almost starving, and some degree of *hæmatemesis*, three or four ounces at a time, had commenced. Immediately after the first use of an electro-magnetic battery, she was able to take some bread and milk, followed by chicken; and three or four applications were sufficient to cure the sufferer. On my return I propose to use it in remittent and yellow fevers.”

F. D. L.

SARATOGA SPRINGS, N. Y., 1875.

HOMŒOPATHY IN THE MICHIGAN
UNIVERSITY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Upon reading the article of Dr. Gerrish, in your issue of September 18th, we could not avoid being convinced of the pertinence of his remarks. We feel sorry that the action of the Legislature and the Honorable Board of Regents should expose the Medical Department to the censure of all, and place the diploma of a deservedly reputable college at a discount. We feel it our duty to call the attention of those holding degrees, to the fact, that our “Alma Mater” is in danger of being placed under the ban of the American Medical Association, and condemned by all reputable members of the profession. Therefore we would suggest that the “Alumni” as a body protest against the joint-stock arrangement. We are not adverse to give these “self-styled martyrs” a chance to prove the *fallacy* (for fallacy it will *prove* to be, as can be ascertained by examining the statistics of its trial in Europe) of their ideas; but we protest against this “silent partner” arrangement. Let homœopathic anatomy, physiology, chemistry, obstetrics, and gynecology be taught by *brethren*, not by those whose *practice* illustrates that “*similia similibus curantur*” is entirely fallacious and not capable of demonstration.

We only feel desirous of setting the “ball in motion,” and would apologize for advancing these few crude ideas.

J. W. BROWN,

Class 1873.

BROCKETTS, N. Y.

DR. H. A. BUTTOLPH, late Superintendent of the New Jersey Asylum for the Insane, has been appointed Superintendent at the new State Asylum at Morris-town, N. J.

THE LONDON MEDICAL SCHOOLS commence their next session on the 18th of October.

THE INDIA-RUBBER CATHETER.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—I hasten to report, for the benefit of my brethren who are often in straits by reason of patients with enlarged prostate, the success which followed the use of the new (Jaques's patent, I believe) india-rubber catheter.

Dr. W. A. Smith, of this city, was attending a gentleman, aged seventy-eight, with retention of urine from enlarged prostate, and failing to relieve him with the usual means, my partner (Dr. J. D. Bromley) and myself were called in consultation.

We used the aspirator (Potain's) several days in succession, of course relieving the patient, but not restoring the natural evacuation. Happening to mention the case to Dr. Dennis, of this city and Bellevue Hospital, he suggested the use of the new catheter, and was good enough to forward me one, with which I entered the bladder in less than a minute. It was a most surprising as well as satisfactory result; for though Dr. D. had assured me of the advantages of this instrument in case of stricture under his observation, as well as of prostatic hypertrophy, still it seemed little likely that an instrument so very unstable and limp would find its way through the urethra to the objective point.

Hereafter I shall try the new catheter in retention before resorting to the (hitherto best method) the aspirator.

Yours truly,

ALEX. N. DOUGHERTY, M.D.

NEWARK, N. J., September 8, 1875.

STIMULANTS IN TETANUS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The following brief account of the treatment, with favorable results, of two cases of tetanus, occurring in the practice of my brother, Mr. Theodore Outerbridge, V.S., may prove of interest to the profession generally, as tetanus has always been regarded as fatal in nearly all cases.

The first case was one of our own ponies. Tetanus resulted from the prick of a nail in one of the hind hoofs. At the first symptoms of the disease the usual remedies in such cases were employed for a week or ten days; no good results ensuing, he (my brother) tried alcoholic stimulants, in the form of old rum and whiskey. This was kept up for about a month, giving about one pint a day, with light fodder, warmth, etc., etc.; the pony, a mare, gradually improved under treatment, and is now as well as ever she was, no troublesome complications ensuing.

The second case was a colt, on which he had performed castration; the owner allowed the stable to get wet, and tetanus resulted from exposure. In this case no other medication, except stimulants, was employed; attention was paid to ventilation, warmth, etc. This case resulted even more favorably than the first, and the colt is now all right.

Sir Thomas Watson, in his lectures on tetanus, alludes to stimulants, and advised the use of wine, and narrated a story (in illustration) of a gentleman who owned a favorite horse, which, being taken with tetanus, he treated him with wine; the horse got well, but he drank more wine than he was worth. In the two cases stated, the liquor used cost about 5 per cent. of the value of the animal.

Although no advocate of stimulants in the general

treatment of disease, yet I would advise the trial of *pure* alcoholic liquors in the treatment of tetanus in the human subject, provided he could be induced, like the equine species, to forbear its use when no longer required; for, unfortunately, the abuse of alcoholic stimulants is one of the curses of our fair islands, which, were it not for diseases induced thereby, would be the healthiest spot on earth.

Yours respectfully,

AGGEE OUTERBRIDGE, M.D.

PLATT'S VILLAGE, BERMUDA, August 25, 1875.

THE RANK AND PAY OF THE HOSPITAL STEWARDS OF THE ARMY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The hospital stewards of the army have long been endeavoring to bring before Congress a statement of their grievances, but have found no champion in that honorable body to advocate their claims. The hospital stewards of the army are, as a class, men of professional abilities, and being pharmacists is required by "Army Regulations." They are required to be sufficiently well versed in clerical duties to prepare all the reports, returns, and keep the necessary registers and record-books of the hospital. They are required to superintend the cooking in the hospital, purchase the necessary provisions for the sick, and see that all articles of extra diet ordered by the surgeon are prepared properly and given at a proper time. They are required to take charge of the hospital clothing and bedding, seeing to its being neatly laundered, mended, and changed upon the beds. He has charge of large and valuable stores of medicines, instruments, and everything pertaining to a hospital, and he is held accountable for their proper preservation and storage. It is required of them that they must be adept in all branches of minor surgery and ordinary dental operations, application of bandages, dressings, etc. The whole charge of the dispensary devolves upon the steward, he must fill all prescriptions for patients in and out of hospital, and is responsible that medicines for those in hospital are administered at the hours ordered. In many instances he is called upon to prescribe as well as dispense. In one instance to my knowledge, at a garrison where the medical officer was only at the post at intervals, owing to other duties some distance away, the steward labored through three epidemics among the children at the post, attending those of officers as well as men, and having as high as eighteen cases under care at one time, and to the satisfaction of the patients as well as the surgeon. Now for these duties, which are not few or light, a hospital steward receives thirty dollars monthly, and allowances but little better than a private soldier. He is an enlisted man, and is compelled to look among enlisted men for associates. He is looked down upon by the officers and must pay them the most subservient homage, although he may be the steward's inferior in length of service, education, and, in many instances, gentlemanly qualities. In fact, in some posts his position is unendurable. He is a gentleman by education, and is compelled to look for associates and friends among those who, as a general rule, are far below him socially, or be without either. His professional acquirements are ignored, and he is classed among the "hewers of wood and drawers of water"—a mere *thing*, to be used and cast aside until further needed. For services which in civil life would bring him a handsome income, in the army he is compelled to render for a laborer's pay.

Every staff department in the army are more liberal to their subordinates than the medical, while none require one-half the qualifications it does.

The navy has recently recognized the "Apothecaries" (the grade identical with that of steward) by an order that allows them *sixty-four* dollars a month and the usual allowances, and for lighter duties, as he has no hospital establishment to look after, no large stock of medicines, etc., to care for, and the *very largest* part of the steward's duties he knows nothing of—I speak of the prescriptions filled for the wives and children of officers and men. This is a constant source of labor to the steward, there being four times as many prescriptions written for them than for the men of the command.

The apothecary has also the privilege of wearing citizen dress, and has a neat and tasty uniform that does not render him liable to be mistaken for a Fenian field marshal by the quantity of green trimmings on them.

Will not some one stand the champion of the stewards and represent their case to Congress? All they ask is rank enough to secure the treatment of gentlemen, and a remuneration corresponding with the knowledge required and labor rendered. They ask to be recognized as a corps of gentlemen, not mere laborers.

CADUCEUS.

Obituary.

ERNST KRACKOWIZER, M.D.

This well-known and universally esteemed surgeon died at his summer residence at Sing Sing, N. Y., on the 23d of September, of peritonitis, following typhoid fever. Dr. Krackowizer was born December 3d, 1821, in Spital am Pyhm, in the Archduchy of Upper Austria, and attended school in Kremsmünster, in the same province, from 1828 to 1831, continuing his studies in the Gymnasium and Lyceum of the same place for eight years. In 1840 he commenced the study of medicine at the University of Vienna, from which, five years later, he received the degree of Doctor of Medicine, one year of the time having been spent at Pavia, in Lombardy, Italy. The next two years were spent at the Institute for Operators, under the direction of Dr. F. Schub, Professor of Surgery in Vienna—this Institute of Operators being peculiar to the Austrian monarchy. Every two years each province enjoys the right of sending two doctors of medicine, who, by a previous theoretical and practical examination, have shown that they possess more than a common knowledge of surgery and aptitude for operating. These, being formed into a class, receive private instruction from the professor of surgery in operating on the cadaver during the first year, and during the succeeding year of their pupilage perform operations on the living subject at the surgical clinic before the students of the university. After completing this course of practical instruction he was appointed assistant to the surgical chair, but was soon compelled to flee from Austria, on account of the termination of the German Revolution. Dr. Krackowizer made an effort to establish himself as lecturer on surgery at the University of Tübingen; but, in consequence of his political antecedents the ministry refused to approve the nomination of the medical faculty. For a time he travelled in European countries, but in 1850 he emigrated to the United States, arriving in New York on the 28th of June. He first established himself in Wil-

liamsburgh, Kings county, N. Y., from whence he removed to New York City in the fall of 1857. He resided for the next five years at 49 Amity street, afterwards at 16 West 12th street, and still more recently at 138 W. 34th street. During his residence in Williamsburgh he edited, in connection with Drs. Roth and Herzka, the *New Yorker Medicinische Monatschrift*, which however, continued but one year. The year before his removal to this city he was appointed Physician to the Brooklyn City Hospital. In New York he held similar appointments in the German Dispensary and Hospital; in the Mount Sinai Hospital; in the old New York Hospital, and for a short time in 1874 in Bellevue Hospital, previous to the recent reorganization. He was a member of the Medical Society of the County of N. Y.; of the N. Y. Academy of Medicine; of the Pathological Society; of the Medical Library and Journal Association; of the N. Y. Physicians Mutual Aid Association, and of the N. Y. Society for the Relief of Widows and Orphans of Medical Men, in most of which he had been an office-bearer, and in all an active member. He was Honorary Member of the N. Y. Public Health Association; Member of the American Medical Association, and, at the time of his death was one of the delegates of the Academy of Medicine to the State Medical Society.

Aside from the numerous cases presented by him at the Pathological Society, reports of which have appeared in the *Amer. Medical Times* and *THE MEDICAL RECORD*, we are able to refer to a few more elaborate papers: A Case of Staphylococci; Treatment of Habitual Scoliosis; Remarks Concerning Syme's Amputation at the Ankle-Joint. While the Surgical Section of the N. Y. Academy of Medicine was in active existence, he prepared several subjects for discussion, *e.g.*, Resection of the Knee; Treatment of Gunshot Fractures; Tracheotomy in Croup; The Operation for Harelip, and he was selected to open the discussion which took place before the Academy on Pyæmia, and the American Medical Association, in 1867, appointed him to report on Local Anæsthesia.

Another feature of Dr. Krackowizer's life was the earnestness with which he interested himself in the political questions of this day. Few among the German population of this city had so great an influence in the party with which he allied himself, and none were more distinguished for unwavering piety and honor.

He had few equals as a physician or surgeon, and when he joined in the discussion of questions which were brought before societies whose meetings he attended, the unvarying attention with which his few and generally practical remarks were listened to was an indication of the value his professional brethren placed upon them.

Although his practice was extensive, his habits of benevolence prevented the accumulation of any considerable fortune. He leaves behind him many who will remember him as a benefactor in the broadest sense.

At a meeting of the Medical Board of the New York Hospital, held September 24th, 1875, the following resolutions were passed:

Whereas, It has pleased an inscrutable Providence to remove from his sphere of usefulness in this world, in the prime of manhood, and the fulness of his powers, Dr. Ernst Krackowizer, our late associate in this Board; therefore,

Resolved, That in the death of Dr. Krackowizer this hospital has lost one of the ablest counselors and most accomplished surgeons that have ever adorned its staff.

Resolved, That as his associates we are called upon

to mourn the loss of one whose personal character and exceptional attainments and ability have always commanded our highest admiration and most implicit confidence.

Resolved, That the death of our lamented colleague creates a void in the ranks of our profession which will be long and deeply felt, and that the example of his loyalty to his high calling, his rare attainments and rich experience have contributed in an eminent degree to elevate the standard of professional excellence in this community.

Resolved, That a copy of these resolutions be transmitted to the family of the deceased, and be published in the medical journals.

At a meeting of the Board of Directors of the Mount Sinai Hospital, held Sept. 26th, 1875, the following preamble and resolutions were unanimously adopted:

Whereas, It is with heartfelt regret that we have learned of the death of our esteemed and respected friend, Dr. Ernst Krakowizer, who for the past sixteen years has been attached to the medical staff of this institution. In view of his great ability and faithfulness be it

Resolved, That we deeply deplore the loss of Dr. Krakowizer, whose services for a long period of time have been of inestimable value to this Hospital. We recognize his fidelity to duty, the super-eminent character of his services, his wise counsel and amiable disposition.

Resolved, That we tender to his widow and family our heartfelt sympathies for this great affliction they have been called upon to sustain.

Resolved, That this preamble and resolution, signed by our president and secretary, be published, and a copy forwarded to the family of the deceased.

E. B. HART, *President*.

N. LITTAUER, *Secretary*.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Sept. 18th, 1875, to Sept. 25th, 1875.

HUNTINGTON, D. L., Assistant Surgeon.—By S. O. 192, c. s., A. G. O., Sept. 22d, 1875, assigned to duty as Attending Surgeon at the Soldier's Home, near Washington City.

PHILLIPS, H. J., Assistant Surgeon.—By S. O. 188, Hdqrs. Mil. Div. of the Atlantic, granted leave of absence for two months, on surgeon's certificate of disability.

TAYLOR, M. K., Assistant Surgeon.—By S. O. 179, Hdqrs. Dep't of Texas, assigned to duty as Post Surgeon, San Antonio, Texas, to date Sept. 1st, 1875.

O'RIELLY, R. M., Assistant Surgeon.—By S. O. 187, Hdqrs. Mil. Div. of the Atlantic, granted leave of absence for one month.

WILSON, W. J., Assistant Surgeon.—By S. O. 190, c. s., A. G. O., Sept. 20th, 1875, granted leave of absence for one year, with permission to beyond sea.

NAVY.

Sept. 21st.

PENROSE, THOMAS N., Surgeon.—Detached from the practice ship *Constellation*, and placed on waiting orders.

BOYD, J. C., Assistant Surgeon.—Detached from the practice ship *Constellation*, and placed on waiting orders.

PAINTER, J. E. R., Acting Assistant Surgeon.—Ordered to duty in charge of medical stores at Nagasaki, Japan, per steamer of 30th inst. from San Francisco.

Sept. 23d.

PEARSONS, REMUS C., Assistant Surgeon, has reported his return home, having been detached from the storeship *Onward*, at Callao, Peru, and has been placed on waiting orders.

SEIGFRIED, C. A., Assistant Surgeon, has reported his return home, having been detached from the *Richmond*, South Pacific Station, and has been placed on waiting orders.

Sept. 24th.

BRADLEY, GEORGE P., Passed Assistant Surgeon.—Ordered to the Navy Yard at Norfolk, Va.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

Monday, Oct. 4th.—N. Y. Neurological Society, College of Phys. and Surg., cor. 23d st. and Fourth av.

Thursday, Oct. 7th.—N. Y. Academy of Medicine, 12 W. 31st st.

Friday, Oct. 8th.—N. Y. Medical Library and Journal Assoc., 107 E. 28th st.

NOMINATION OF OFFICERS FOR THE COUNTY SOCIETY.—At the meeting of the Medical Society of the County of New York, Monday evening, the following nomination of officers for the ensuing year was made, to be voted on at the Annual Meeting in October. *President*, H. B. Sands (by J. C. Peters), T. Addis Emmet (by C. S. Wood), J. C. Peters (by J. O'Sullivan). Dr. Peters declined to serve, and moved the closure of the nominations. *Vice-President*, T. Addis Emmet (by J. C. Peters), J. C. Peters (by J. O'Sullivan). Dr. Peters declined to serve, and moved that the nominations be closed. *Recording Secretary*, A. E. M. Purdy (by Hanks). *Corresponding Secretary*, F. A. Castle (by Hanks). *Treasurer*, H. P. Farnham (by Dr. Chadsey). *Censors* (five to be elected), H. T. Hanks (by W. T. White), Charles Heitzman (by Tauszky), Charles P. Russell (by —), J. C. Peters (by Hanks), J. E. Janvria (by Castle), Paul F. Mundé (by Hanks), William T. White (by Purdy), E. Eliot (by Farnham), F. V. White (by —), C. S. Bull (declined to serve), Charles Packard (by —), Edward G. Janeway (by —), C. M. Allin (by —), T. T. Sabine (by —). Dr. Farnham moved the nominations be closed.

Delegates to State Med. Soc. in place of Dr. A. Jacobi, elected permanent member: T. H. Satterthwaite, Beverley Robinson, William T. Lusk, L. D. Bulkley, C. C. Lee, A. McL. Hamilton.

CORRECTION.—In the list of teachers in the medical schools included in the table on page 636 of THE MEDICAL RECORD for September 18th, the following corrections need to be made. H. E. Webster's name should be entered as Professor of Physiology, instead of George T. Stevens; and the name of J. V. Lansing, as Professor of Theory and Practice of Medicine, the latter having been entirely omitted.

In the "Order of Lectures," Prof. A. B. Crosby should lecture on Wednesday, Thursday, and Friday at nine o'clock, and Prof. W. T. Lusk on the remaining days of the week at the same hour.

Original Lecture.

ON THE TREATMENT OF TYPHOID FEVER.

By W. H. THOMSON, M.D.,

PROF. OF MATERIA MEDICA AND THERAPEUTICS IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

LECTURE I.

GENTLEMEN:—We said in our last lecture that acute diseases had many of the characters of accidents in their nature, course, and termination. Chronic diseases, on the other hand, are most commonly due to inherent vices in the constitution itself. The human system is endowed with remarkable powers of repair in the case of accidents, and the reparative processes are definite in their character and in the periods necessary for their completion. In keeping with this fact we find that acute diseases are commonly recovered from by regulated processes, which are frequently as well marked and self-limited as the steps in the mending of a broken bone or the healing of a wound. Chronic diseases, on the other hand, like cancer, epilepsy, or phthisis, often seem to rise spontaneously, or in many cases of unfortunate families they cannot be prevented, be they guarded against never so carefully. And moreover, in that one word chronic lies the unwelcome intimation that the system cannot, by its own powers, recover from them, but needs help from outside, if help there be.

An excellent illustration of what an acute disease is, and also how an acute disease should be managed until the system can recover itself from it, is to be found in the case of typhoid fever. The cause of typhoid fever, in the first place, is as foreign to the congenital tendencies of its victim as a railway collision; for an inhabitant of a coral island in the Pacific, who has not yet come into communication with the outside world, is no more likely to be prostrated by it than he is to be run over by a locomotive. Moreover, when this fever does prevail, it is not the infirm nor the aged who are the most liable to be attacked by it, but rather, in all countries, young adults, and those who have enjoyed the best average degree of health. Lastly, when it is once fairly developed in a case, there is no more use in attempting to cast it out than there would be in planning to unite the ends of a broken radius by artificial cement. We must wait for the system to deal with the fever as it does with a fracture, and our whole duty is restricted to the following aims: 1. To watch against special hindrances or complications in the normal course of the affection; and 2. To assist the suffering system in its own efforts and processes of restoration.

First, therefore, what are these special hindrances or complications which you are likely to meet with, and therefore should be on the watch for, in guiding a typhoid-fever patient through his illness? Keep in mind the illustration which I used about the part to be borne by the physician in the management of a case of acute disease, that it is similar to that of a cool-headed man with a runaway horse, namely, that he had better not try to match his strength against the horse, but rather keep him in the middle of the road. You should know the road well beforehand—that on this side is such a ditch, on the other such a turn or such a stump, and by a timely pull on this rein or on that avoid each special danger, until the wearied animal slackens his pace of

his own accord. Those dangers in the case of typhoid fever I would class as follows:

1. Dangers from the pyrexia or fever heat.
2. Dangers from starvation.
3. Dangers from self-poisoning, due to imperfect or perverted excretions.
4. Special dangers from morbid agencies, such as malarial infection, visceral inflammation, etc.
5. Accidents, such as from intestinal hemorrhage, perforation, etc.

I. PYREXIA.

This we put first because in no acute affection are the special disorders caused by a fever temperature alone, so likely to be met with and to kill as in this complaint. If I were asked to name the greatest contribution to practical medicine from the researches of modern pathologists, I would have little hesitation in citing this of the kind of textural damage caused by a rise from the normal degree of blood heat. Be the cause of fever heat what it may, yet that heat will occasion certain definite alterations in the body, proportioned to the amount of that heat. I do not refer by this statement to the degree at any one time in the thermometric rise, so much as to the sum-total in the course of each particular febrile affection. Those changes may be briefly described as consisting in a destructive alteration of the proper cells of the tissues affected, and in the properties of the blood. Thus the blood becomes viscid and sticky, and prone to be very dark in color. The voluntary muscles first become dry and deeper in color; then the fibrils granular, and then, thus losing their striated appearance, fatty or waxy, breaking easily, and ultimately wasting away, in some cases to an extreme degree. Just such a change also appears in the muscular tissue of the heart. In the liver, the hepatic cells break up into similar granular and fatty masses. The kidneys also undergo a precisely analogous degeneration; while the lymphatic and ductless blood-glands, such as the spleen, etc., enlarge, become softened, and may end in being most extensively disorganized. An excessive blood heat, however, acts with special severity on the nervous pulp itself, as we might expect. In deaths occurring in the course of febrile affections, marked by an extraordinary rise of the thermometer, the dying itself is by coma; but in all cases where the fever has been both high and long-continued, we find very frequently fatty degeneration of the nerve-fibres, with softening and pigmentary alterations in the ganglion cells; very commonly great cerebral œdema, and not infrequently actual atrophy of the brain itself indicated by diminished size of the convolutions.*

Now we infer that these and many similar parenchymatous degenerations are the direct results of high temperature, because they are to be found in a great number of different febrile complaints, such as pneumonia, cerebral rheumatism, scarlet fever, typhus, etc., in proportion to the degree of heat which has been developed in their course; and likewise in no complaint more than in typhoid fever itself. But in death occurring in this disease without any antecedent excess of heat above the average,—as, for example, in some cases of intestinal perforation,—we will find them absent, or less pronounced, according to the same condition. How much of the symptomatology of typhoid fever proceeds from these changes we will have occasion to note more fully as we speak of the measures which we should adopt to avoid destruction from pyrexia. The next great danger is

* Hoffman, cited by Liebermeister, on Typhoid Fever, Ziemssen's Cyclop., vol. i.

2. STARVATION.

It is strange to what a degree this peril of typhoid fever is overlooked. Of course you rarely read any observations on the treatment of this affection without finding recommendations to give proper nourishment to the patient; but the special need for attention to this indication, and an explanation of the causes of the starvation which the disease produces, are but imperfectly described. Yet it is always doubtful how many of the symptoms which are enumerated as characteristic of its course may not be due directly to the inability induced by it on the part of the alimentary canal to prepare food enough for the suffering system. I have often asked myself the question, Suppose a healthy adult were strapped down in bed for fourteen, twenty-one, or twenty-eight days, and allowed nothing but swallows of that innutritious liquid, beef-tea, what symptoms would be likely ere long to be present? Let a man go without eating for only four days and he will look as if he had been suffering from a wasting fever; if for a longer period, then the same restlessness and inability to sleep, the same rapid, weak pulse, the same forms of muscular and glandular degeneration, the same tremor of the hands, and perchance the same muttering delirium, or even the same diarrhoea, with ulceration of the bowels, which have been regarded as pathognomonic of typhoid fever: all these have repeatedly been shown to occur as symptoms or results of simple starvation. Now it is well in this connection to recognize the true genesis of a fever starvation, for it proceeds directly from the derangement of all secreting glands by a rise in the temperature of the blood from the normal point to which they have been adjusted for the performance of their functions. There can be no doubt that one of the chief purposes subserved by that remarkable power of the living body of maintaining a uniform thermometrical degree, no matter how extreme the fluctuations of external temperature may be—so that the same blood heat is noted on the arctic shores as in the hottest countries of the globe—is to maintain an unvarying point of distillation, as we might term it, from the blood, for the vast glandular apparatus. The secretions of glands are all very complex organic fluids, and we know that even in the comparatively rude processes of our laboratories, nothing is more important in the preparation of organic fluids than a careful attention to the point of distillation; for let that point be passed but a few degrees and the products will be very much modified, if not entirely changed from what we intend. Now, whenever we note a rise of blood heat, from whatever cause, we will also simultaneously note a perversion or a suppression of glandular secretion throughout the body. At first the skin becomes dry and parched, there is thirst in the mouth, and constipation of the bowels, with scanty urine. Meantime the patient becomes incapable of digesting solid food, and if this be administered to him it causes distress and aggravation of his symptoms, not because meat and such like articles are too "heating," as was once supposed, but simply because there are no digestive secretions in the alimentary canal to deal with them, so that for the time being solid food acts as if it were a foreign body to that canal, and can occasion nothing but harm from its presence. The digestive powers of the patient are reduced, during the continuance of the fever, to more than the weakness of infancy, and hence it becomes one of the most imperative duties of the physician to deal intelligently with the complications which arise from this source with special frequency in the case of typhoid fever, also, owing to its own marked tendency to affect, primarily, the glandular apparatus of the in-

testinal tract. Another difficulty, proceeding from the same cause, is that the absence of the normal digestive juices in this case deprives the system of the natural antiseptics for preventing fermentation and decomposition of the matters present in the stomach and bowels. Both the gastric and intestinal juices, when added even in moderate quantities to meat, milk, and other putrescible substances, will keep them from fermenting in the open air for considerable periods. Now I can scarcely resist the conclusion, especially as it seems supported by the effects of certain therapeutical means which I will soon detail, that a great proportion of the diarrhoea, and of the intestinal ulceration of typhoid fever, is owing to the irritation caused by the acid fermented matters present in the bowels, and therefore that measures specially conducive towards preventing such fermentation, by the administration of artificial digestive solvents, should be systematically employed during the whole course of the disease.

3. DANGERS FROM SELF-POISONING, ETC.

Arrest of general secretion by altered temperature of the blood, of course involves the dequating or excreting glands equally with those of the alimentary canal concerned in digestion. A necessary result of this complication is, that the blood soon becomes charged with effete matters, whose retention must ere long produce symptoms of poisoning. In those febrile affections whose course is marked by a sudden defervescence, or what is usually termed a crisis, we sometimes have a fall take place in the fever of five or more degrees in a few hours, and, coincident with this, not infrequently there supervenes a free discharge from the bowels, or a great increase of deposits of urates in the water, or a profuse perspiration. Formerly these "critical discharges," as they were termed, were regarded as efforts on the part of the system to throw off or eliminate the poison of the fever, and unfortunately, acting upon this imaginary hint from nature, the profession was at one time possessed with the idea that a fever patient should be vigorously purged, sweated, and made to urinate freely, or worse yet, salivated, till, as Boerhaave directs, he should expectorate two pounds of saliva a day! The disastrous sway of this elimination theory probably has more to do with the successful rise and progress of homeopathy than any one influence chargeable to the regular profession. We now know, however, that the simple explanation of these critical discharges in fevers is, that the previous defervescence enables the emunctory glands to resume their suspended functions on the return of the blood to its normal temperature, and that, owing to the large amount of accumulated excrementitious matters, their action for a time is unusually brisk; for that it is not an act of elimination of the special poison is shown by the fact that the discharges do not contain anything diverse from the ordinary products of those secretions; for the urine in scarlatina, for example, does not contain any scarlatinal agent; that, on the contrary, still lurking in the skin, the same as in small-pox. Meantime it is the physician's part to guard against self-poisoning by a judicious and moderate employment of measures calculated to keep the emunctory glands up to their accustomed duties, and we will show that even in typhoid fever such cathartics as calomel, used with discrimination, and a careful attention to the functions of the skin, will have a marked effect in lessening the rate of mortality from this fever, a fact whose explanation I believe to be in the lessening of the proportion of those ingredients in the circulation which afford the best pabulum for the reproduction of the fever virus. This

indication is peculiarly pressing in the case of patients past middle life, for as the glandular structures are the soonest of all others to grow old, so all fevers, and notably typhoid, are proportionately more fatal as age advances, and it is unquestionable that many of the peculiar nervous symptoms developed, even at comparatively low temperatures, in such patients are largely the effects of poisoning by retained excretions.

4. SPECIAL DANGERS, ETC.

As to our fourth class of dangers, from the operation of other morbid agencies modifying or complicating the course of this malady, I would state that the existence of many chronic diseases, such as phthisis, nervous affections, etc., do not especially influence its course to the degree we might expect. But there is one cause of disease especially prevalent in this country which seems to act along with a typhoid infection to such an extent as materially to affect its development and course, and that is the ague malaria. So commonly is this the case that some physicians maintain that we have a distinct typho-malarial fever, which partakes equally of the characteristics of both fevers. At any rate, you will frequently meet in our hospitals in New York, as well as in private practice, with cases of fever marked by the same enteric or abdominal symptoms as typhoid, including also the characteristic intestinal lesions found after death, and presenting the same eruption during life, but in which the course of the fever, as marked by the thermometer, is quite different from that of a typical case of typhoid. These are not by any means necessarily severer cases than those of ordinary typhoid, as I have had frequent occasion to note, especially in my wards at the Roosevelt Hospital, but in some instances they are. I have lately lost a patient, a young lady, who, after suffering from ague for some time, contracted typhoid in an exceptionally severe form. In her case the highest temperatures, instead of occurring as usual in the afternoon or evening, always occurred in the early morning between 4 and 6 A.M. After guiding her through the typhoid for four weeks, the fever, as expected, began to show signs of decline, when I was suddenly disappointed by a great rise one morning, which continued some thirty hours, and then began to subside; seven days afterwards another morning rise occurred, then in seven more days another, and then, for the fourth hebdomadal, another, with the same suddenness, and this time occasioning fatal collapse on the fifty-fourth day of her illness.

Such cases show the need of a careful review of your thermometric observations, so that when a marked periodicity is revealed in the recurrence of certain symptoms, you should recognize who the enemy is that is making mischief, and deal with him appropriately. We will now leave the subject of the prophylaxis of the accidents of typhoid, above alluded to, to be considered under the head of the treatment of the sequelæ of the disease, and pass at once to the measures to be adopted for neutralizing the dangers arising from the first-named source, namely, the pyrexia.

MEASURES FOR SUBDUGING THE PYREXIA.

To deal with this danger it is as absolutely necessary to be provided with one instrument as it is to have an eye for seeing where you are going, and that is the thermometer. In the case of some acute diseases the value of the indications which the thermometer affords has been much exaggerated. In diphtheria or in meningitis, for instance, its importance is very secondary.

But with typhoid fever I have felt a pity for myself and my patients when I remember how in former years I treated hundreds of cases of it in the Quarantine Hospital, in ignorance of the information which the thermometer can impart. By the thermometer you can, in the first place, detect that you have typhoid to deal with, and then soon come to a conclusion whether you are going to have a severe contest with it or not. But as we have no time now to diverge from the strictly therapeutical aspects of our topic, I will say that it is in the recognition of the special dangers to be apprehended from the pyrexia in each case, and of the best methods for combating those dangers, that you will find it both invaluable and indispensable. By it alone you may be able to know that the patient is on the brink of destruction from a literally burning brain, when others are not aware that such peril is near. I was once asked by a physician of extensive practice, and much my senior, to see a young man who had been ill seriously more than a week with this fever. I was assured that there was but a moderate amount of fever, and yet the patient had become unaccountably nervous and at last suddenly comatose, though the surface was cool and the pulse low. I found cool hands and feet, sure enough, but my thermometer in his axilla rose to above 107° F., and in less than half an hour afterwards he died. It has been since the employment of this instrument becoming prevalent in the profession that the great advance has been made in the knowledge of the mode of causation of those fatal lesions in febrile affections which we have alluded to, and hence has furnished us with one of the chiefest indications for treatment. It is not too much to say that the thermometer, therefore, has changed the place of typhoid fever from ranking as one of the most fatal of acute diseases, almost to the low level of measles, and added to the gratifying assurance of the physician that his profession offers him something better than the rôle of a sagacious gazer at his patient, such as the expectant school of twenty years ago were fain to make him. For not only do we now cast about for true apyretics, or fever-lesseners, but we have found them, and, moreover, by the thermometer we have found out how to use them as they should be used.

First among these, our present means for lowering fever heat and saving our patient's vital organs from its mischief, I would put the employment of external cold by means of packs, affusions, and baths. Considering the plain facts of the case, it is rather surprising that spite of the earnest advocacy of the English physician Currie, nearly two centuries ago, of the use of cold as an apyretic, the profession allowed its faith in drugs to go so far as to neglect its employment up to a late date. This may have been due, however, to the fact that until the thermometer revealed the true action of cold in fevers, this powerful agent may often have appeared to operate in a very perplexing and uncertain fashion, for its effects, after all, are not so simple as they might appear at first sight. To begin with, the initial effect of immersing the body in a cold bath is to *raise* the temperature, as indicated by the thermometer in the rectum and under the tongue, and not to depress it; in other words, actually to increase rather than to decrease the fever.

This rise in a cold bath is noticeable both in health and in fever, and I have known it to amount to a full degree. Hence, if the patient is removed too soon from the bath, before the continued operation of the cold has had time to overcome this initial rise in the heat, on getting him back to bed you are disappointed at finding that his fever seems to be worse than ever. Continue the immersion, however, long enough, or add

ice till the temperature of the bath falls from, say 70° F. to 65° F., or 62° F., and sooner or later, according to the severity of the case, the fever gives in, and the body heat begins to sink. It may take a long time, for I once had a typhoid case in which the patient lay in a bath of 62° F. to 65° F., up to the neck, with an ice-bag on the head, for fifty-four minutes before the thermometer fell a fraction.

Now, when the thermometer begins to fall, renew your observations of it every two minutes or so, that is, put it back under the tongue two minutes after you have withdrawn it for noting the register, and let it remain three minutes *in situ* each time. If it sinks rapidly, that is, if two degrees are lost in five minutes, or three degrees in ten minutes, then, no matter what the figure at which it still stands, you ought to remove your patient without delay to his bed. Certainly do not think of keeping him there till the temperature falls to near the normal point in a very cold bath. The reason for this rule is, that the temperature goes on sinking after the patient is removed from the bath, often for more than an hour, and the longer generally in proportion to the length of the immersion. Hence he may pass from the extreme of fever to the extreme of collapse, from prostration by cold, and some cases even of death from this cause have been reported in England, following the employment of cold against cerebral rheumatism. But there is not the least danger of such a mishap in typhoid, if only you follow the directions which I have laid down, because after a considerable experience I believe I can pronounce cold apyretic baths among the safest therapeutic agents we possess, if properly employed.

If you aim at bringing down a fever from 104° F., or 105° F., you should be content with the figure 101° F. or 100° F. at the most in the bath, for the thermometer will then sink to 99° F. or 98° F. afterwards. If, however, the time to produce a fall has been prolonged, say between twenty minutes and half an hour or more in the bath, then I would remove the patient while the thermometer stood at 102° F., for the effect of prolonged cold with many patients is to make them feel uncomfortable from it for some time, even though the heat does not sink afterwards below 99° F., and occasionally I have been obliged to use hot bottles to the feet, and give several swallows of brandy and water, because of seeming prostration, with the thermometer still at 99½° F., under the tongue. If the temperature falls in the bath rapidly after only a short immersion, as I have seen it do in less than ten minutes, from 106° F. to 99° F., then you may be pretty sure that it cannot be typhoid fever in its first week, but some other complaint. The idea of such a plunge, however, you will always find to be more or less terrifying at first to the patient or to the friends. It appears to be so heroic a style of treatment that it requires a good deal of confidence in you to have them acquiesce, and a confident demeanor on your part in recommending it. The first few baths the patient generally objects to moreover; but very soon the good effects of this measure are so apparent in lessening the worst accompaniments of the fever, that not only do the friends cease to object, but very often towards the close of the fever you will become annoyed with the importunities of the patient for more baths than you may deem prudent. I have even held out the prospect of an ice-water bath as a reward for good behavior in taking food or medicine. Where the patient dreads the first impression of cold, Ziemssen's plan is a very good one, namely, to commence with a bath about 80° F., and gradually cool down, by adding ice, to 65° F. The patients frequently shiver a good deal in the water,

but if the heat still marks high you need not pay much attention to this symptom. Meanwhile, it is always advisable to douche the hot head with pitchers filled from the bath, only do so gently, and hold the pitcher but a few inches above the head, because, in distinction from other douches, you are not seeking here the powerful irritation of the blow of falling water, but refrigeration simply, and you will find this measure specially grateful in the beginning of the disease, during the period of headache, as well as in those cases where the delirium is very active. The cold pack is much less effective than the cold bath, but towards the decline of the fever, or when the patient is too weak for moving, it becomes very useful. My usual plan is to wrap the patient first in a sheet wrung out of simple cold water, and then over this to lay a sheet wrung out of ice-water, this second sheet to be renewed as often as it becomes warmed, but not the first, and to continue the application until the required decline has been attained.

Now, what are the effects of this treatment, and how often shall we prescribe the dose? In severe cases of typhoid fever you will generally note the refrigeration to last about an hour, and then the thermometer commences slowly to rise again, so that by two or three hours it reaches its former point. If so, then I would recur to the bath again every two hours, or twelve baths if possible in the twenty-four. In such a case, it may be, that nothing but this measure will save the patient's life. But much more commonly you will find that you have broken the high range for three, or four, or six hours, or even for a day, so that you need but four, three, or two baths. The thermometer alone is to be your guide, for you should begin with a resolution that you are not going to allow the patient to have a fever above a certain point, say 102° in the morning, and 103° in the afternoon, or still lower according to the nature of the case. Hence in severe cases it is just as essential to give the baths during the night, or during the day, and you will never have cause to regret such pertinacity on your part in following up the pyrexia for the whole time. The symptoms of the patient will soon show you that you are doing well by your perseverance. After the bath the patient is a great deal quieter, his delirium in nearly every instance either improves or passes off altogether, to return only with the renewed rise of the thermometer. The breathing becomes easy and natural, the pulse improves, and often the sufferer drops into a quiet sleep accompanied by a gentle perspiration. But what is of special significance is, that the course of the thermometric range itself of the fever, in the majority of patients, becomes permanently lowered to a point at which the chief perils of the disease will hardly be met with. You seem to be pursuing a different road from the well-known track of typhoid fever. Instead of those numerous features, such as clouded intellect, muttering delirium, subsultus, etc., which, when they occur in the course of other febrile complaints, we may hear that the patients have lapsed into the typhoid state, your cases will frequently remain with but little change from day to day, through the second and third weeks, from their symptoms at the end of the first week, and, to the great relief of the attendants, but rarely pass their urine or motions in bed.

PERFORATING ULCER OF THE DUODENUM.

By DANIEL F. COLLINS, M.D.,

NEW YORK.

THERE is scarcely any disease coming under the observation of the physician of which so little is known as to its origin as that of perforating ulcer of the duodenum, the chief causes of our ignorance being that the disease is of comparatively rare occurrence, and when it does present itself it is not always recognized. The principal works on diseases of the digestive system are almost silent on this subject, merely mentioning the existence of such a disease and its very fatal nature. Such being the state of our knowledge respecting this malady, it seems important that all cases of it coming under our observation should be carefully considered. The following case will be found both instructive and interesting in many respects:

Jacob Wenzel, aged thirty years, German, of low stature, and stoutly made, while working in a factory was hurt by the falling of a piece of lumber. He was confined to his bed for one week with pains in his stomach, hips, and chest, from which he said he completely recovered.

On June 20th, 1874, about one year from the date of the above occurrence, he was suddenly attacked, while at work, with pain in his stomach, vomiting, and weakness, and was obliged to leave off work on that account. On June 23d, three days after he became sick, I was called to see him in haste, as the messenger said he was in a dying condition. On arriving at his house I found him sitting up in a chair, breathing with difficulty, face pale, skin of a dirty yellow color, and quite cold and clammy to the touch. Pulse 60, and very weak. He was vomiting every few minutes, and could not retain even a spoonful of cold water on his stomach. On examination I found his abdomen very much distended and hard, and on pressure being made he complained of great pain over his stomach. He stated that his bowels had not moved for four days, although he had taken medicine, and he seemed to think that the cause of his trouble.

After ordering some medicine to check the pain and vomiting, and an injection to relieve the loaded condition of his bowels, I cautioned him against taking large drinks of ice-water and milk, which he had been doing all day, and being unable to retain anything on his stomach, the vomiting caused by these drinks very much increased his suffering and danger. Next day word was sent to my office that Wenzel got out of bed about six o'clock in the morning, and walked across his room and drank nearly a pint of feed milk, and in returning back to bed fell on the floor and expired in a few seconds.

At a post-mortem examination, nine hours after death, I made the following notes: Body muscular and well developed; skin yellowish color; abdomen very much distended and hard. On opening into the abdominal cavity a large quantity of purulent serum escaped, and the intestines seemed floating in it. Heart rather above natural size, but perfectly healthy; lungs presented a normal appearance; stomach slightly congested, particularly near the pyloric orifice. About three inches below the pylorus, on the anterior surface of the duodenum, was a perforation half an inch long by one-eighth of an inch wide. The edges of this perforation were even, and presented but a slight trace

of inflammatory action; the appearance of the intestine around the perforation was natural. The intestines contained a quantity of fetid fluid, the smell from which was almost unbearable; liver slightly congested; kidneys healthy.

Before entering into a consideration of the above case the following extracts on this subject from the principal works on the practice of medicine will not be out of place. Dr. Flint, in his work, makes the following remarks in relation to this disease:

"It is a curious fact, ascertained by Curling, that a sloughing ulcer is apt to take place at the upper part of the duodenum within a few days after the occurrence of a severe burn on the skin; perforation may occur under these circumstances. Ulceration of the duodenum is not a constant effect of a severe burn. Wilkes states that he failed to find it in several cases which had come under his observation."

In Tanner's Practice of Medicine, page 430, the following account is given:

"Perforating ulcer of the duodenum presents many of the symptoms of an ulcer of the stomach, but in a mitigated form, consequently fatal perforation occasionally takes place suddenly when the patient has made but little complaint;" and Dr. Tanner goes on further to state that this ulcer is often found in cases where death has resulted from severe burns. In Bennett's Practice of Medicine the only mention made of this disease is the history of a case, page 789, which resembles in so many particulars that of Jacob Wenzel, that I quote its important features:

"James Abernethy was admitted to hospital with a large swelling and ulceration of his left hand. After admission his urine became like porter, and his feet and legs began to swell; these symptoms were preceded by rigors, but he complained of no pain. The œdema continued to extend, and in three weeks dyspnoea came on. He had no appetite, but great thirst. Abdomen was distended and fluctuating; skin anasarous, that over the back pitting on pressure; left arm from elbow down one mass of ulceration. This man was sick about a year, when he died." *Post-mortem*.—"Both lungs anasarous, with coherent pleure, which, on being separated, the pulmonary texture broke up, being rendered soft by chronic pneumonia; liver showed signs of several calcareous concretions; kidneys pale yellow color, slightly mottled with vascular patches; on section of kidneys the cones were unusually congested. One inch below the pylorus the duodenum was perforated by a round ulcer, and around it were several patches varying in size from a three-penny piece to that of a shilling; the peritoneum contained about half a gallon of serum." Dr. Bennett concludes the history of the above case with the following remarks: "Following a prolonged ulceration of the arm, there supervened nephritis, general anasarca, and œdema of the lungs. What, however, constitutes a remarkable feature in this case is the presence of a chronic ulcer in the duodenum, which had not been manifested by any symptoms whatever."

The case of Jacob Wenzel resembles in many particulars the foregoing. In Dr. Bennett's case the patient lived a year from the date of his being attacked with ulceration of the hand, during which time he never complained of any trouble of the stomach or bowels, and if we admit that the injuries received by Wenzel from the falling of a piece of lumber upon him was the origin of his trouble, both cases were of the same duration.

Towards the end in both cases there was the same difficulty of breathing, thirst, and swelling of the abdomen. In Dr. Bennett's case the urine of the pa-

tient is described as like porter, and the skin as anasarca. Nothing like this showed itself in Wenzel, as his water was perfectly normal, and there was no anasarca of the skin. These differences in the symptoms of the two cases will be readily explained by the post-mortem appearances, for we find in Dr. Bennett's case that the porter-like water, swelling, and general anasarca were the result of nephritis and chronic pneumonia; while in the case of Jacob Wenzel no such complicating diseases were present to produce these symptoms. In neither of the above cases did the patient suffer any pain or uneasiness in the digestive organs from the commencement of their trouble until immediately before their death, although pain is an often recurring symptom in perforating ulcer of both the stomach and duodenum.

Dr. Budd, in his Treatise on the Stomach, states in a few pages devoted to the consideration of perforating ulcer of the duodenum, page 148: "The chief symptom of ulcer in the duodenum is pain in the situation of the ulcer, which is seldom constant, and which in most cases is felt only two or three hours after a meal, when the food is passing from the stomach into the duodenum. From the symptoms being usually much less severe than in ulcer of the stomach, the fatal perforation usually occurs with still less warning." The case of Wenzel is also instructive in a medico-legal point of view from the following circumstances: Wenzel, the day before he became sick, got some cathartic medicine at a drug store to relieve constipation. The medicine not having produced the desired effect, and he suddenly becoming sick, alarmed both himself and his friends, who believed that he had been poisoned by the druggist, and it was with difficulty that his friends could be made to understand the nature of his disease, and the innocence of the drug clerk. A good deal of discussion has taken place from time to time as to the primary seat of this disease. I think an examination of the collected cases will prove, first, that the perforating ulcer is nearly always found within the first three inches of the duodenum. Secondly, it is well proven that it is in this portion of the intestinal canal that the glands of Brunner are most numerous. Thirdly, in nearly all cases where death has been caused by this disease, an examination of the intestine has given ample proof of the enlargement and inflammation of these glands. On considering the above, there seems to be sufficient ground for the belief, that these glands are the principal and primary seat of the disease in question.

Prof. Geo. B. Wood, in his work on the Practice of Medicine, states (page 615) when considering the subject of duodenitis: "Perforation sometimes takes place from simple ulcer, as in the stomach from gastric ulcer, with fatal effect. The appearances are so similar to those in gastritis as not to require particular notice except in relation to the mucous glandules, or, as they are often called, the glands of Brunner, which are very numerous in the duodenum near the pylorus, and in inflammation of this viscus are apt to be enlarged, exhibiting sometimes elevated, irregular, almost continuous patches of considerable extent."

The above description of the appearance of the intestinal mucous membrane after death from duodenitis resembles the post-mortem appearances seen in Dr. Bennett's case very closely, both exhibiting the same irregular patches, etc., and should the condition of the intestine described by Prof. Wood have gone on until ulceration had set in, the post-mortem appearances in both cases would be identical. In an article published in the Cyclopædia of Practical Medicine, page 266, "On Organic Diseases of the Stomach," Dr. Houghton

gives two explanations as to the mode in which inflammation is set up in the glands of Brunner. He says: "This form of ulceration arises at one time on their surface by their direct irritation and ulcerous absorption, while at others it seems to succeed upon their internal swelling from obstruction to their follicular orifices."

The above quotation explains itself. Dr. Houghton not alone holds that the glands of Brunner are the primary seat of the disease, but explains two conditions under which simple irritation may give rise to inflammation and ulceration in these glands. First, by irritation of the structure of the glands; secondly, by closure of the follicular orifices of the glands, and the distention caused by the collection of the secretion within the gland. This disease, unlike perforating ulcer of the stomach, seems to attack males much more frequently than females. It would seem that any occurrence tending to the irritation of the pyloric orifice or the upper portion of the intestinal canal may be looked upon as an exciting cause. The published cases of this disease go to prove that a large number of the victims were accustomed either to the free or immoderate use of alcoholic stimulants, and we may with little hesitation class alcohol as one of the principal causes of perforating ulcer of both the stomach and duodenum. This disease has also followed as a result of severe burns on the skin, but as yet no satisfactory explanation for this occurrence has been given. An anæmic condition of the system has been considered by many as one of the causes of this disease. This supposition is, I hardly think, confirmed by statistics bearing upon the subject, as in a majority of the cases I find reported, where death has resulted from the disease, the victims were found to be robust and in apparent good health. Perforating ulcer of the duodenum has been found in two or three cases where death has resulted from malignant disease of the uterus and appendages. Dr. Budd, "Diseases of the Stomach," page 151, relates the history of one case, a woman twenty-two years of age, who had "an enormous compound ovarian cyst of the right ovary." No intestinal disorder showed itself until a few days before death, when vomiting and purging suddenly set in. On a post-mortem examination being made, the condition of the intestinal canal was found to be healthy, except in the duodenum, where two large ulcers were found. Dr. Budd says: "The appearance of the uterus, as well as the recent occurrence of the intestinal disorder, indicated that the ulcers were of recent formation, and thus raised the suspicion that the tumor had in some way or other been instrumental in causing them."

239 EAST 34TH STREET.

NEWARK DISPENSARY FOR WOMEN.—A dispensary devoted to the treatment of the diseases of females has been opened at 466 Broad street, corner of Orange street, in Newark, N. J., of which the attending physicians are: A. Mead Edwards, William O'Gorman, Frank Wilmarth, and Miss K. Parker as assistant. Tickets have been issued to responsible persons, to be given to women in need of treatment and worthy of assistance from a charitable institution, on which the endorsement of the giver is asked, as a guarantee that the interests of the charity are being carried out in the manner intended.

A NEW HOSPITAL IN PARIS.—A new hospital is to be opened toward the end of this year in the "Ménilmontant" quarter of Paris, from which the hospital is to be named. It is to consist of one hundred and fifty beds, and is to have a lying-in service attached. The quarter is one of the poorest in Paris, and is much in need of hospital accommodations.

DISLOCATION OF RADIUS AND ULNA OUTWARDS.

By W. C. C. ANDREWS, M.D.,

OF THE RESIDENT SURGICAL STAFF OF BELLEVUE HOSPITAL.

THE following case is interesting chiefly in its rarity, and is recorded because it is one of the first, if not the first, of its kind reported by an American surgeon, viz., a pure and complete dislocation of the radius and ulna outwards. The latest American authority upon fractures and dislocations says that but eleven similar cases are on record, and all of the eleven occurred to French surgeons.

Gustave S., admitted to Ward 11, Aug. 12, 1875, 1.30 A.M., aged 17, single, U. S., engraver.

Patient is a strong, healthy youth, who fell from a shed two hours before admission. The distance fallen was only eight feet, and the substance fallen upon a manure heap. It was afterwards found that the manure covered a pile of stones, and was about one foot thick. Patient says that he struck upon his right side, the right arm lying beside and partly under him—the elbow being straight, or nearly so. The skeleton shows that the elbow must have been flexed at least 30° to admit of such a dislocation without fracture of the olecranon.

Examination immediately after admission showed a very characteristic deformity—simple inspection being largely diagnostic. As no swelling had occurred the bony points were so beautifully distinct that the only doubt was with reference to a fracture complicating the dislocation. One of our visiting surgeons, and nearly all of the hospital staff, examined the arm carefully and confirmed the diagnosis, which seemed unquestionable.

The forearm was at nearly a right angle with the arm—the hand resting upon the thumb in a position of forced pronation. The abrupt bulging of the forearm forwards and outwards was very marked. As usual in these cases, both the biceps and triceps were uncontracted and entirely flaccid. Externally the olecranon was easily felt—the finger slipping over its convexity and dropping into the great sigmoid cavity. This alone seemed to exclude fracture of the process, and the relaxed triceps, without any chip of bone in its substance, confirmed the supposition. Above, and to the inner side of the ulna, the round head of the radius was plainly felt, and rotated normally within the lesser sigmoid cavity when the hand was supinated. Projecting very strongly upon the inner side of the joint, and on a plane with the flattened posterior face of the arm, was the inner condyle. Both the epitrochlear process and the trochlear surface were distinctly felt, and the absence of fracture here easily shown. The outer condyle lay deeply beneath the head of the radius, and could only be detected upon firm pressure. Hard crepitus, indicating fracture, was carefully sought for, but could not be obtained.

The soft parts seemed to have escaped injury, excepting the capsular and lateral ligaments, which must have been extensively torn. There was but little swelling—no ecchymosis, and no appearance of rupture of muscles. The hand was warm, and did not feel numb nor sleepy to patient. Good pulsation existed in both the radial and ulnar arteries. The arm was laid comfortably in an open wire splint, and lotio plumbi et opii applied.

13th, 5.30 P.M.—Patient was thoroughly etherized to produce complete muscular relaxation. Fracture was again carefully looked for, but not found. An assistant made counter-extension from the humerus,

another grasped the forearm, with his thumbs against the olecranon, the hand was then supinated and the forearm made nearly straight with the arm. Extension followed, during which the elbow was gradually flexed and olecranon pressed inwards, when both bones slipped readily into place, and the reduction was accomplished. Very little force was used. Reduction was accompanied by the usual soft snapping between the articular surfaces. For the third time fracture was looked for and not found. All the normal motions of the joint were restored and perfect, though somewhat loose. The head of the radius seemed very prominent and free in its movements, although it had always retained its natural relations to the ulna. Arm was replaced in sling, and lead and opium wash continued.

The rarity of this case seemed to justify the long delay of reduction, so that the visiting surgeons might all see and examine it. It is to be regretted that so many of these were out of the city, and that swelling and commencing ulceration through the tightly stretched skin over the internal condyle made further delay dangerous.

14th.—No signs of inflammation, but in anticipation of it a week's rest will be allowed the arm, with the constant application of lead and opium wash.

21st.—No pain nor inflammation. Daily passive motion.

28th.—Sling discontinued; arm of normal size; motions of joint nearly perfect, except flexion, which only extends to a right angle. Patient thinks that he can use his arm, and is anxious to go home.

30th.—The patient's notoriety has become too much for his modesty, and he has absconded.

Progress of Medical Science.

COUDEREAT'S OPERATION OF TOTAL ABLATION OF THE UTERUS THROUGH THE VULVA.—Dr. Coudereat describes an operation which he recommends for cancer of the uterus, and by which he claims to be able to remove the entire womb by the vulva without opening the peritoneal cavity. The operation consists in drawing the uterus forcibly downwards, by means of an instrument which he calls an endoceph, aided to a certain extent by the knife, and finally enclosing the structures above the prolapsed womb in two ligatures between which the ablation is effected. The endoceph, as he terms the instrument which he has devised for this operation, is formed of two branches, which are joined together like the obstetric forceps, but instead of crossing each other, as in the latter instrument, they separate at either end like the branches of the letter X, and when the two handles are approximated the opposite extremities diverge. The instrument is passed into the cavity of the uterus, the shape of the branches being adapted to the purpose, with knobs at the ends which fit into the cornua. This instrument enables the exercise of a powerful traction without tearing through the tissue of the womb, as happens when forceps are used which simply grasp the neck. After the instrument has been introduced the external extremities are made to approach each other until a sufficient sense of resistance is produced, when they are fixed by means of a screw which prevents the branches within the womb from diverging any further. The endoceph being in position, the neck of the uterus is drawn towards the vulva as

far as the laxity of the tissues will permit. The precise relations of the anterior vaginal wall with the bladder are ascertained by introducing one finger through the urethra, which has previously been dilated. A circular incision of the vagina is then made upon the neck, taking care that it be below the point at which the bladder has been ascertained to lie, and avoiding the peritoneal cul-de-sac which covers the vaginal wall behind. The vagina is dissected for a slight extent from the uterus with the bistoury or scissors. Then, with the end of the finger, the bladder is pushed up and the cellular attachments of the peritoneum are separated as far up as possible. Meantime an assistant makes traction upon the endocephs to assist in the dissection, the direction of the traction being always downwards and backwards. The union of the peritoneum with the posterior vaginal wall is so intimate that no attempt can be made to separate them without danger of opening the peritoneum. The connections, however, yield a little and, finally a considerable prolapse is effected behind (in consequence of the continued tractions) as well as in front. Then, by means of small forceps attached to the external anterior wall of the womb, as near the fundus as possible, the uterus is brought well down, and while it is maintained in this position a ligature is applied above, forming a pedicle, which includes (1) in front, the vesico-uterine cul-de-sac, which has been detached and pushed back from the base of the organ; (2) at the sides, the broad ligaments with the uterine vessels; (3) behind, the utero-rectal cul-de-sac. An iron pin is passed through the pedicle, and behind it another ligature is applied and tied moderately tight. The uterus is then removed by the bistoury. The vagina is closed with five or six metallic sutures, leaving the pedicle outside till it separates, when the vagina is pushed back into the pelvic cavity.

EFFECTS OF DIVISION OF THE OPTIC NERVE.—Dr. V. Krenchel has repeated Dr. Berlin's experiments of dividing the optic nerve of the frog, and obtains results quite contrary to those of that observer. It will be remembered that the latter found that this operation produced a direct accumulation of blood in the retinal vessels; the retina assumed a whitish cloudiness, and often became separated from its attachments; sometimes there were marked inflammatory changes of all the retinal layers, and, finally, granular degeneration of the optic nerve fibres. Occasionally the whole eye was destroyed by inflammatory action.

Krenchel also observed these changes when the operation was performed by Berlin's method; but he shows that this is due to the section of the vessels in the nerve and the ciliary vessels, which is unavoidable by that method. He found that he could divide the nerve within the skull, and thus avoid wounding the vessels. He incises and shoves back the mucous membrane of the pharynx, so that the optic chiasm can be seen through the thin bones, a little posterior to the equator of the eye, and divided with a small pair of sharp scissors. He found that in frogs thus operated on, for six months after the operation there was no change in the eye, either by ophthalmoscopic or microscopic examination. With polarized light the fundus was likewise found to be normal. The fundus was always dark whenever the two nicols had the position in which the reflex of the corneal tissue disappeared; only the red veins of the hyaloid could be seen over the black ground, due probably to the fact that all the light coming out of the eye is reflected by the retina. The white streak of the retinal vessels then disappears, which proves that the light comes directly

from the smooth upper surface of the retinal vessels, or from the blood column, as indicated by Prof. Donders, and not from reflection from the fundus oculi and refraction by the vessel, as asserted by Loring. In the latter case it should, just as in the remaining parts of the fundus, be depolarized, and can, therefore, not disappear by turning the nicols. K. found that the circulation of the blood in the vessels of the hyaloid remained unchanged, and that the retina and pigment layer retained their normal appearance. The fibres of the optic nerve were always found to be normal. In a few cases, however, there was a fatty degeneration of the nerve filaments, though only one to two millimetres from the point of section. Most of the animals were kept alive five to six months, but it is very probable that the nerve layer of the retina would degenerate after a longer period. Lehmann says that fourteen days after the destruction of the nerve within the cranium, the nerve layer has already disappeared; but it is not possible to recognize delicate changes in the frog's eye by his method of examination.

Berlin states that the pupil contracts in his method of operating, and remains contracted for several days; it then dilates and remains dilated. Krenchel found that the pupil, even after several months, retained a certain mobility to light, although it does not contract nearly so long or so rapidly as before. This agrees with the fact known since the investigations of Brown-Séquard, that even in extirpated frog's eyes the iris reacts to light, although more weakly than in intact animals. By this method of dividing the nerve without injury to the nutrition of the eye the pupil does not contract, and what is more remarkable, the mobility on the penetration of light is not diminished. Even in animals which had been operated on five to six months previously, accurate and often repeated comparison with normal frogs revealed no difference either in the size of the pupil or in the reaction to sun, day, or gas light.—*Onderzoekingen gedaan in het Physiol. Lab. der Utrechtsche Hoogeschool, Derde Reeks, iii. i.*

CATARRH OF THE BILIARY DUCTS A CAUSE OF ICTERUS.—M. Cornil describes a lesion of the fine microscopic biliary ducts, which occurs in various affections of the liver, accompanied with jaundice, and to which he thinks the icterus is due. He first observed it in connection with cirrhosis. In the midst of the hypertrophied connective tissue, between the lobules, the biliary passages were found lined with their cylindrical epithelium, while the interior of the canal was filled with desquamated epithelium.

The appearances were regarded as indicating a catarrhal affection. The biliary ducts being plugged up in this way, the bile secreted in the hepatic cells has no avenue of escape into the intestine, and hence finds its way into the blood. It is believed that the icterus accompanying different forms of parenchymatous hepatitis is due to a similar condition of the biliary ducts. C. has met with it in cases of hepatitis due to grave fevers, such as variola and periperal fever. Moreover, the icterus occurring in connection with new formations in the liver, like carcinoma, may be similarly explained. Where the disease is accompanied by the development of fibrous tissue about the lobules, the small ducts become affected in the same manner as in cirrhosis, and it is only necessary that a sufficient number of ducts should be implicated for the icterus to be produced.

It was further observed that whenever there was a complete retention of the bile the hepatic cells became affected with a fatty degeneration.—*Gazette Médicale de Paris, July 31, 1875.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

W.M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, October 9, 1875.

A VACANCY IN A HOSPITAL STAFF.

ANOTHER vacancy has been created in the attending staff of one of the metropolitan hospitals. Every time such a state of things occurs we are reminded of the necessity of reform in hospital appointments, and are inclined to indulge in the vain hope that justice will be done and merit be rewarded. The exceptions to the rule which should govern such appointments have, however, become so glaring of late, that the most sanguine wisher for better things is well-nigh discouraged. The more important the position to be filled, the more difficult does it seem to separate it from the controlling influences of some one of the more powerful medical cliques. The assumed right which the colleges have of making the first choice, is now so much of an acknowledged fact that the outside profession submit to their dictation without question. Far from giving any reasonable chance for honorable competition for positions in any hospital staff, the filling of vacancies in certain of the large charities are all farmed out beforehand. We have every reason to believe that we shall have another illustration of the fact in the disappointment of many worthy applicants, who may in their innocence suppose their chances to be reasonably good for the vacancy to which we have referred. In the effort to gain enviable positions a large majority are sure to be disappointed, but the vanquished in an honorable fight have generally the melancholy satisfaction of explaining their defeat either to the ordinary accidents of battle or to the inexorable law which governs the doctrine of the survival of the fittest. That neither of these conclusions is always true in reference to hospital appointments, is quite apparent to many who have had experience in the matter.

All sorts of suggestions have been offered to change the existing state of things, but practically little of anything has been accomplished. Attempts have been made to initiate a reform founded upon the system of

concours which has prevailed abroad, but seemingly to no purpose. The difficulty which presents itself at the very outset of such a consideration is the formation of an examining board which shall be sufficiently unprejudiced and sufficiently competent to decide upon the merits of the respective candidates. A Committee of Examiners might be made by some one or more of the medical societies, but it is notoriously true that almost all these associations are managed by gentlemen who are too incompetent for any other kind of work, and who are too willing to devote themselves to the interpretation of parliamentary laws and to the usual tricks of petty politicians. These medical Warwicks are usually so bent upon the accomplishment of petty schemes, that it is quite difficult to convince the more scientific portion of any body that the motives of their action are beyond question or not open to some suspicion. Under the circumstances there would be no guarantee that any satisfactory examining board could be appointed. The chances are ten to one that these petty politicians would vote themselves in as the censors, and so effectually monopolize the offices as to keep them in the lowest grades of designing cliquism. If it could be otherwise, we should make a very proper start towards establishing a concours which would tempt the best minds in the profession to the competition for hospital places.

It is certainly to be deplored that the medical profession, either from its inability to settle upon some reasonable understanding that should insure fair play in these appointments, or its general lack of interest in a subject of such vital importance to its members, should place itself so completely in the hands of laymen, virtually constituting the latter as the judges of medical qualifications. As the matter now stands the managers of our hospitals have the absolute right of appointing whoever they may choose. As a consequence, there is a temptation on the part of applicants to stoop to measures which tend towards sycophancy, meanness, and trickery, and which naturally beget a contempt for the claims of really meritorious men.

Not long ago there was a promise of a change in the manner of these appointments, by an avowed intention on the part of the Commissioners of Charities and Correction to respect the wishes of the profession in the matter. To such an end they proposed to receive nominations for hospital places from responsible medical sources. It was soon discovered, however, that although the outside profession might be satisfied with such an arrangement, the interests of the colleges were in an opposite direction, and after a vain attempt to reconcile differences, to quiet animosities between the different schools, and restore harmony in the medical staff, the attempt was finally abandoned as hopelessly utopian.

The neglect to properly advertise existing vacancies in the hospital staff is another radical fault in the system of appointments. An opportunity would thus be given for every one who believes himself qualified

to serve the various institutions, to put in his claims. Now, as we have before intimated, hardly any one but the ring managers knows of a vacancy until it is filled. In fact we have known of appointments having been made to supply vacancies before the funeral of the previous occupant.

By allowing every one who chooses to apply an opportunity so to do, the managers can at least relieve themselves of a good deal of the responsibility which they assume in making their choice, and not restrict themselves to a few who may appear to them to be the only ones who desire a position. We are willing to do our part in furtherance of such a plan of action by gratuitously advertising any vacancies. In the present instance the writing of this article was prompted by the vacancies created in the hospitals in which the late lamented Dr. Krackowizer served, and as we have reason to know that such a vacancy in the New York Hospital is not yet filled, we take occasion to state that all competitors for the position should at once send in their applications to the Board of Governors of that institution, and judiciously and dignifiedly urge their respective claims without delay, and may the best man win.

SHALL IT BE A PROFESSION OR A TRADE?

IN spite of the practical progress of pharmacy, and the predictions of a noble future for it, the question we propose must sooner or later be settled. Is devotion to pharmaceutical science and art to be a mere matter of dollars and cents, or is it to be the indication of a keen sense of moral obligation to the community on the part of a fraternity of educated professional intelligence? We are disposed to believe that the pharmacists of the United States are not yet fully prepared to accept the latter alternative. The confession embodied in the remarks of the Permanent Secretary at the recent meeting of the American Pharmaceutical Association, that it was impossible to check the sale of patent medicines, even by respectable druggists, because the public insisted on purchasing them, is an illustration in point on which to base a belief that over-sensitiveness of the pocket nerve, which is so marked a characteristic of human nature, may possibly keep pharmacy in the list of commercial rather than of professional pursuits. A more noble course was clearly outlined at the meeting in 1874, when in the course of the President's address it was urged that "the time has already arrived when the pharmacist is required to be something more than an artisan, if he desires to perform his duties intelligently and in accordance with strict scientific principles; otherwise he is a pretender without the hope of honor, a detriment to the public good, and an obstacle in the way of his more progressive brother. The pharmacist is required to be a merchant and a professional practitioner of his science, and by this subsidy of interests he is frequently found incapacitated to harmonize his several duties. Those who aspire to equal honors in the two phases of their

business experience should carefully guard against that rock upon which so many have been wrecked, and which constitutes an impediment to progress. By uniting the two interests on a just and generous platform, and letting them serve as handmaids to each other in harmonizing diverging interests, very much can be accomplished towards advancing commercial and professional pharmacy." But in what way can these widely diverging interests be harmonized? Assuredly not by inaction and by a simple begging of the question in tamely confessing that druggists must persist in perpetuating a great public wrong, by yielding to an unreasoning demand for remedies, the ingredients of which are often unknown to both buyer and seller. Some of the semi-medical preparations thus sold have long since been proven by analysts to be possessed of positively deleterious if not absolutely poisonous properties; and yet, because the public, so called—a name which in this case is almost a synonym for the non-educated portion of the community—seek them, the druggist finds a convenient excuse for indulging in a traffic that is pecuniarily profitable.

In the Annual Report of the Board of Health of Boston, for 1874, we find an analysis of various hair-dyes and restoratives, cosmetics, enamels, etc., which, although not strictly coming under the class of patent medicines, are frequently sold by the apothecary. From an examination of the compounds first mentioned, the conclusion is arrived at that, as a rule, the use of these preparations is attended with much risk, from the absorption of lead into the pores of the skin, and thus into the system; while some of the familiar cosmetics "are nearly as dangerous as any toilet preparation can be made," one of those examined containing three virulent poisons in considerable quantity. We believe the best method to be pursued in order to bring the unreflecting portion of the public up to a proper standard of education on this subject is for the respectable apothecary to refuse peremptorily to sell for purposes of therapeutic efficacy, or even of mere external beautification, any compound of whose construction he is ignorant, or which he does not know to be innocuous. Until this happy millennium arrives, pharmaceutical associations may labor in vain to attain the elevated status they covet on the professional pedestal, for pharmacy will remain, in spite of the enthusiasm of its thousands of well-wishers, and of its numerous excellent and honorable scientific partisans, mainly a commercial occupation, around which will hang only the aura of professional perfection. Any halfway measure, such as was proposed at the recent meeting, in which it was suggested that a bulletin or health-almanac shall be issued, giving information as to the composition of patent medicines, will be incomplete, unsatisfactory, and impracticable. As a rule, the public will not care to see these publications; will not read them when they see them; and will not understand the points of danger involved when they read them.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, September 16th, 1875.

DR. S. S. PURPLE, PRESIDENT, IN THE CHAIR.

AFTER the reading of the minutes of the last stated meeting, the President delivered a brief address of welcome to the Academy on this the first session after the usual summer vacation, in which he directed the attention of the fellows to some of the work before them to be performed during the coming winter, and chiefly relating to the discussion of certain important medical questions.

In the course of the librarian's report, which followed, it was announced, after acknowledging the receipt of several valuable books, that the President of the Academy had placed in the library about two thousand bound volumes of periodicals.

Before proceeding to read the paper for the evening, Prof. Isaac E. Taylor presented what he called an entirely unique specimen which he denominated

HÆMATOCELE OF THE AMNION.

The placenta was delivered at eight months. The hemorrhage had taken place between the chorion and amnion, and the amnion could be distended by means of a blow-pipe sufficient to cover a surface six and a half or seven inches in diameter. The specimen was regarded as analogous to one reported by Cazeaux; but in Cazeaux's case the hemorrhage was between the placenta and chorion. The umbilical cord was attached to the thin delicate amniotic membrane, and when the specimen was removed the bloody distention of the space between the amnion and chorion was about the size of a large egg.

PROF. TAYLOR then proceeded to read his paper upon the question,

"WHAT IS THE BEST TREATMENT OF CASES OF LABOR WITH CONTRACTED PELVIS?"

The subject was divided into two sections as follows:—What is the best treatment in cases of contracted or deformed pelvis with a diameter from $2\frac{1}{2}$ or $\frac{3}{4}$ to 4 inches, and second, Is craniotomy preferable to Cesarean section in cases where the diameter of the pelvis ranges from $2\frac{1}{2}$ or $\frac{3}{4}$ to $1\frac{1}{2}$ inches?

To the first question he directed the attention of the Academy at this meeting, and proposed to discuss the second on some future occasion. In order to solve the question under discussion he proceeded to consider which operation is preferable in this class of cases—version or the use of the forceps—and also studied the advantages which these operations have, the one over the other. There are two important points which should always be kept in view in the study of the question, namely, that operation is to be selected which will most conduce to the safety of the mother; and second, if possible, craniotomy is to be avoided.

The Professor then proceeded to recite the history of two cases, one with a uniformly contracted pelvis, and the other with a simple, flat, non-rachitic pelvis. By the simple, flat, non-rachitic pelvis is meant one in which the deformity is at the superior strait alone; and by the uniformly contracted pelvis is meant one which exactly comports with the word used, and is uniformly smaller than normal. The variety is believed to be much more common than is generally supposed,

and is to be regarded as the real cause of delayed delivery in many cases of so-called tedious labor. The conclusions arrived at, with regard to the management of these two classes of cases, were that in the simple, flat, non-rachitic pelvis the forceps should first be resorted to, and if found impossible to effect a delivery by this means, then resort to version; while in the uniformly contracted pelvis the forceps should be employed, and in case the operator fails, then resort must be had to craniotomy or cephalotripsy. The professor argued that in these cases operative interference should not be delayed, as urged by many obstetric writers, until the child dies, but should be undertaken early.

With regard to version and forceps the opinion was expressed that the assertion that the former could be resorted to earlier than the latter is untrue.

Cases were cited in which he had applied forceps through an os uteri very thin, and dilated to only $\frac{1}{2}$ of an inch in diameter, not large forceps for the purpose of effecting delivery, it is true, but forceps constructed in a peculiar manner, by means of which the head could be held in such a position as would enable it most effectually to secure the dilatation desired, and when this was accomplished then the larger instruments were applied and the child quickly delivered.

Finally, the question of the induction of premature labor was referred to, and the belief expressed that the results following this operation are not so unfavorable as one would be led to suppose by reference to the writings of very many observers.

The discussion of the paper was deferred until the next meeting of the Academy.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, September 27th, 1875.

DR. THOMAS ADDIS EMMET, VICE-PRESIDENT, IN THE CHAIR.

AFTER the reading of the minutes of the last meeting the Chair announced the names of Drs. John Kinkead, William Fernbach, and Patrick Lynch, as reported by the Comitia Minora for membership, and the report was adopted.

The death of Dr. Krackowizer was then announced and a brief outline of his medical career read by Dr. Emmet, who appointed a committee, consisting of Drs. Jacobi, Rudlich, and Eliot, to draft appropriate resolutions.

The following names were placed in nomination for officers of the Society:

For President—Drs. Sands and Emmet.

For Vice-President—Drs. Emmet and J. C. Peters.

For Recording Secretary—Dr. A. E. M. Purdy.

For Corresponding Secretary—Dr. F. A. Castle.

For Treasurer—Dr. H. P. Farnham.

For Censors—Drs. Hanks, Heitzman, Russell, J. C. Peters, Janvrin, Mundé, W. T. White, Eliot, F. V. White, Packard, E. G. Janeway, Allen, and T. T. Sabine.

For Delegate to State Medical Society, to fill vacancy—Drs. Satterthwaite, B. Robinson, Lusk, Bulkley, Leale, and A. McL. Hamilton.

Amendments to the by-laws were reported, which are to be printed, sent to the members, and voted upon at a future meeting.

DR. BEVERLEY ROBINSON then read a paper upon

POST-NASAL CATARRH,

which is briefly summarized as follows:

This disease, which has been regarded as a simple one, has baffled the efforts of those who have made a specialty of it and kindred affections, and has not had its pathology accurately described. Post-mortems with reference to this affection have, from its nature, been very few, and clinical observation has not yet afforded us all that we need, hence our knowledge concerning it is necessarily imperfect. The best means for the examination of a case consists of a small mirror, a reflector, a tongue spatula, and a good light. As to whether the disease is a local or constitutional one, must be decided by clinical observation; but notwithstanding its very great prevalence and its apparent attacks and course, unaffected materially by habits or occupation in many instances, he was convinced that unless a special constitutional tendency existed in the individual, he would but rarely become subject to the disease. In other words, it is not a simple, acute, or chronic inflammation of the pituitary membrane, but a certain diathetic condition is necessary to its existence.

Chronic post-nasal catarrh is to be regarded as nothing more than a chronic follicular disease affecting the mucous membrane lining the naso-pharyngeal space, and is essentially the same as chronic follicular disease of the throat and air-passages. It is characterized by (1) a sensation of stuffiness and oppressive fulness in the superior and posterior nasal passages, and (2) by a falling down of a greater or less quantity of mucus, which varies in physical character from simple mucus to muco-pus, that becomes hardened, takes on a bad odor as the result of decomposition, and finally acts as an irritant to increase the chronic inflammatory processes, produces ulcerative changes in the tissues which may finally go on and affect the bones. It is only by inductive reasoning that we know of the presence of ulcers in the deep recesses of the nasal fossa. The ethmoid cells are probably diseased; but it could not be admitted that the amount of discharge which almost always occurs, comes entirely from them, because they have but few follicles, and it is altogether probable that the follicles of all the post-nasal passages contribute to its production. Hypertrophy of tissue was regarded as a sequela, and in many instances brought on by treatment.

The indications for treatment are constitutional and local, but systemic means were regarded as of prime importance which brings into use iron, quinine, arsenic, strychnia, cod-liver oil, abundance of fresh air, well-regulated exercise, bathing, etc., etc. The local treatment is to consist of the internal use of such remedies as have an effect upon the mucous membrane lining the naso-pharyngeal cavity, and the topical application of sprays and powders for the same purpose. Among the former we have the chlorate and iodide of potash, ipecac, squills, cubebs, copaiba, etc., etc. It much more frequently happens, however, that only temporary relief is obtained until we go behind these and seek for the diathesis which may be present, and address our treatment towards the relief of such constitutional affections, as gout, syphilis, malarial poisoning, tuberculosis, and others equally important.

In systems free from diathesis three remedies had been employed with decided advantage, namely, sulphur, cubebs, and ammoniacum. The sulphur is most beneficial when given by the stomach: in the form of spray it may prove to be an irritant. Cubebs should be continued for some time—for months even—which can be done by omitting the remedy for a few days and then returning to it. Scruple doses were recommended, disguised with syrup of orange-peel or other substance, and given before, or after, or between meals. Ammoniacum in one or two grain-doses, combined

with some expectorant, such as perhaps ipecac, may be added with great benefit in many cases. When dyscrasic affections are present, they are to be treated according to their requirements. With regard to syphilis, small doses of mercury, notably the bichloride and biniodide, and continued for a long time, were recommended. Iodide of potassium was not regarded with favor. As regards

LOCAL TREATMENT,

it was remarked that there is no plan which receives the general endorsement of the profession, and it was believed that local treatment is not so beneficial as it is usually supposed to be. These statements were made in view of the facts, first, that we have no instrument by means of which remedies can be properly applied; and second, that applied in the usual manner they cannot reach all the diseased surfaces. The reasons why the instruments in common use are inadequate for the application of remedies to these diseased surfaces have been set forth in an article written by the author of the paper and published in THE MEDICAL RECORD, August, 1874.

Local treatment, however, is a decidedly powerful adjuvant, but to be this it must be carried on wisely. Not that we can reach the diseased parts, but that it will aid the effect of systemic remedies. Sprays and powders are substituted for the continuous stream of some solution so commonly used, because it is believed that they penetrate the irregular sinuosities of the passages quite as well, are equally useful, and are less liable to do harm. The temperature of the spray should be warm but not too warm, perhaps 70° or 80° F., and it should be concentrated, but not sufficient to be caustic in its action, hence strong solutions of nitrate of silver were rejected. A favorite powder consisted of iodoform one drachm, camphor one drachm, and gum sufficient to make a powder of a required strength, perhaps two drachms. Lastly, local applications are of service in reducing the thickness of the mucous membrane and restoring the glands to their normal condition. The paper was accepted by the Society, and, being open for discussion,

DR. BULKLEY remarked that his attention had been called to one cause of this disease which Dr. Robinson had omitted to mention, namely, functional derangement of the liver. The relation between the latter disease and the one under discussion was made by Dr. Murchison. Dr. Bulkley had noticed the fact in his own person, and turning his attention to the fact in his patients he had found it particularly present in cases of eczema, acne, and psoriasis, which are almost always associated with some disturbance of the digestive apparatus. The post-nasal catarrh is relieved by the treatment of those affections.

Locally, he had seen great benefit derived from the use of steam, loaded with the vapor of benzoin, prepared in the following manner: Throw a drachm of the compound tinct. of benzoin into a pan, perhaps a drachm of laudanum may also be added, and upon these pour a pint of boiling water, and let the patient quickly inhale the steam. This can be repeated very easily by the patient, and can be done a large number of times a day.

DR. BURRALL corroborated the statements made by Drs. Robinson and Bulkley, regarding the constitutional nature of the affection. He was of the opinion that salt water could be applied with great advantage as a lotion to the nasal cavity, when moderate force was employed. He also recommended the use of tr. belladonna, not only for its effect as a local astringent,

but that its action upon the nerves of the parts may be obtained.

The Society then adjourned.

Correspondence.

REMARKABLE RECOVERY FROM GUNSHOT, SABRE, BAYONET, AND SHELL WOUNDS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—To the three cases of "remarkable recovery from gunshot wounds," which you have recently published, I may add one, which, though it does not enlarge the record of bullets penetrating the intestine, will, I think, be considered "remarkable" for tolerance of injury, and for the fortune which guided sword and bullet through vital tissues and organs with wonderful avoidance of the great blood-vessels.

Jacques Roellinger, private, Co. B, 47th N. Y. V., offered himself for examination as a candidate for a pension on the 29th of June, 1865.

The necessary notes for this purpose were taken at that time. It was the only opportunity which I had for seeing him, and duty to other applicants prevented a very prolonged examination of his case.

The points of the following history are transcribed from the notes above mentioned, and the connecting details are given as I remember them. Perhaps some medical officer may correct and extend them.

After the evacuation of Yorktown, in May, 1862, a part of the 47th Regiment was left in garrison at the abandoned Confederate works on Gloucester Point, opposite Yorktown. With them the inhabitants of the Northern Neck, or district between the York and Rappahannock rivers, kept up a guerilla warfare. A picket to which Roellinger was detailed was surprised, and he was wounded, (1.) by a sabre cut, leaving a long scar, which crossed the quadriceps extensor of the left thigh in its middle third. It appeared to have divided the tendinous and a portion of the muscular structures. (2.) By a sabre thrust, which passed between the bones in the middle third of the right forearm. The wound must have healed readily, for in the same season, at Williamsburgh, Va., also while on picket duty, he was shot (3) in the right thigh, the ball passing through the middle third, just external to the femur.

(4.) At the assault on Fort Wagner, in Charleston Harbor, July 10th, 1863, he received a sword cut across the spinal muscles covering the lower dorsal vertebrae. My recollection of the scar is that it indicated division of the tissues for six inches, with some loss of substance. When partially recovered he received a furlough, and went to visit a brother, at that time serving under Gen. Pope, in south-western Missouri. He was there captured by guerillas, and tortured in Indian fashion. (5.) Two broad and contracted cicatrices he declared were the marks left by burning splinters of wood, which were held upon the surface of the right anterior portion of the thorax. Escaping from his captors he presently rejoined the eastern army, and was serving in it at the battle of Olustee, in Florida, on the 20th of February, 1864. Being on the skirmish line in front of the enemy's works, (5) a fragment of an exploding shell passed from without inward beneath the hamstrings of the right thigh, and remained imbedded in the ligamentous tissues about the internal condyle of the femur. I could plainly feel it, ap-

parently encysted there. Of course he fell, and the skirmishers, hastily retiring, left him on the field. Expecting a sally of the enemy, by the aid of some trailing vines he pulled himself up into the fork of a tree, where he hoped to escape further notice. The sally was made; he was seen and fired upon. (6.) The ball entered between the sixth and seventh ribs on the left side, just beneath the apex of the heart, and issued on the right side, posteriorly, near the angle of the ninth rib, traversing a portion of both lungs. Profuse hemorrhage from the mouth followed, and from the wound also, and, fearing that he must soon faint and fall, he slid down from his elevated position to the ground beneath. (He said he was a professional acrobat before he entered the service.) The enemy in turn were now retiring, and, with natural vindictiveness, *moriturus salutarit* with the contents of his revolver. One of their men fell, and one or two of his comrades ran back for a moment to our prostrate friend, whose smoking revolver showed him to be still a combatant. They bayoneted him through the body. (7.) On the margin of the epigastrium, where it merges into the right hypochondrium, I found a depressed triangular cicatrix, the sides of which were about half an inch in length, and, posteriorly, to the right of the spine, and, nearly on the same level, a similar but smaller scar, also triangular, but not depressed. These certainly looked as if they might have been made by the old-fashioned bayonet. If they were so made, that bayonet passed through the left lobe of the liver, and lacerated the posterior border of the diaphragm!

What was perhaps meant for a *coup de grace* was given in the form of a pistol ball, which (9) entered on the level of the angle of the left lower jaw, through the border of the sterno-cleido-mastoid muscle, and issued at the corresponding point on the other side of the neck. He added that during his convalescence he used to amuse the company by drinking and projecting the fluid in a stream from either side of his neck, by simple muscular effort. The ball then crossed the vault of the pharynx.

Perhaps Ponce de Leon's fountain of perpetual youth is somewhere near Olustee; at any rate the man lived most inexcusably, and at some time, I cannot say whether before or after, acquired the further following embellishments, viz.: (10.) The scar of a sabre thrust passing between radius and ulna, just below left elbow. (11.) A pistol shot, passing diagonally outward and upward through the pectorales major and deltoid of left side; and (12.) a deep cut dividing the commissure of the left thumb and forefinger down to the carpal bones.

The greatest disability from all this mutilation appeared to be the ankylosis of the right knee-joint. He did not declare, and I did not determine, any impaired function in the viscera of the chest or abdomen.

When the catalogue was ended this surgical museum politely apologized for his haste, saying that he was on his way to the steamer, intending to join Garibaldi's army, at that time campaigning in the Valtelline.

If any memoir of our civil war more "profusely illustrated with cuts" survives, let us hope that he will stay at home with us, where we can pay him honor and a pension, and not risk his elastic life among Italian brigands.

W. M. CHAMBERLAIN, M.D.

THE PHILADELPHIA MEDICAL TIMES has changed from a weekly to a bi-weekly, and the price of subscription is reduced to \$4.

THE PROGRESS OF MEDICINE IN JAPAN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Among the most interesting events of the present century is the almost universal appreciation and adoption of the modern ideas and appliances of science and art by the Japanese people; and in no departments has the progress been more rapid than in those of medicine and surgery, the teachers and students of which branches have been in no slight degree instrumental in advancing western civilization amid the most observing of the Mongolian nations.

During a recent visit to Philadelphia I had an opportunity of seeing a Japanese translation of the "Manual of Military Surgery" of my friend and clinical master, Professor Gross, a duodecimo volume of nearly two hundred pages, which appeared in the spring of 1861, and was designed to meet the emergency of the occasion, containing, as it did, in a small compass, substantial hints on field, camp, and hospital practice. That the little work was considered worthy of the pen of its distinguished author was shown by the fact that four thousand copies were issued from the press, and that it was included in the supply table of the Army Medical Department.

Through the kindness of Professor Gross I was enabled to take a copy of the letter of Surgeon-General Matsumoto, in whom I recognized an old acquaintance, having met him on the occasion of the visit of the Japanese Embassy to this country fifteen or sixteen years ago.

"Tokio, the 31st May, 1875.

"DEAR SIR:—The deep interest I felt in, and the great value I attached to your precious 'Manual of Military Surgery,' published in Philadelphia in 1862, induced me to engage Messrs. Tokai and Yamaguchi to translate it into Japanese for the benefit of our National Military Surgery. I have the pleasure of sending you herewith such a copy, hoping that you will kindly accept it as a token of our high esteem and profound gratitude for your assistance in promoting the welfare of our military surgery.

"I have the honor to remain, dear sir, most respectfully yours,

"R. MATSUMOTO,

"Surgeon-General-in-Chief of the Sanitary Service to the Japanese Army."

From a letter written to Professor Gross by Mr. Bingham, our Minister to Japan, under date of June 9th, I made the following extracts, as they cannot fail to prove of interest, indicating, as they do, the wholesome influence that is being exerted upon the masses by the members of our profession, both native and foreign. He says:

"I have the honor to send herewith, through the State Department, a letter and package addressed to you by Dr. Bukema, a European surgeon and physician of high repute in the service of the Japanese Government. I was informed verbally by Dr. Bukema, that the package enclosed is a Japanese translation of your 'Manual of Military Surgery.'"

It is another evidence that the world moves to see these dreamy children of the land of the morning appropriating the science and learning of our western civilization, and incorporating into their own language the productions of our foremost thinkers.

It may interest you to know that many persons from Europe and America are in the employment of this Government as instructors of the people in the arts and sciences, the literature and laws of western nations. Among all the foreign nations introduced into

Japan, none, I think, have done more for the material advancement and comfort of its people than the schools of medicine and surgery. These schools are largely attended by the native population, and are chiefly in charge of European and American professors.

As I am informed, these professors have done much by their methods of treatment to lessen and alleviate the ills that these people are heir to. For example, the small-pox, which for ages has been a terror and scourge in Japan, has been greatly checked by the introduction of vaccination. I have been told that one Japanese physician, aided by his assistants, has within three years vaccinated in the city not less than seventy thousand persons. This certainly looks like advancement in civilization and science, and would doubtless make Jenner feel, if it should come to his knowledge, that he had not lived in vain, even for the people of the distant land of the sunrise. In the light of this result how grand seem the words of that benefactor of his race, "I prefer duty in the lowly and sequestered walks of life to fame, that gilded butt forever pierced with the arrows of malignancy." Said it is that Jenner felt these arrows himself, and was denounced for his great discovery as one who would "bestialize society."

I send you this interesting account, Mr. Editor, believing that the medical profession will be glad to know that our science is being so ably advanced in Japan, and to hear of the honor that has been so justly paid to the distinguished professor of our own country.

I am very truly yours,

MORRIS J. ASCH, M.D.

33 W. 31st St., Sept. 20, 1875.

"UNSUCCESSFUL PRACTITIONERS."

TO THE EDITOR OF THE MEDICAL RECORD.

MR. EDITOR:—In order to succeed it is as necessary for a young practitioner to remain long in one place as it is for him to be well educated, and had "Diploma" been satisfied with his first year's experience in New York, and remained there, I think he would have won the success he merited.

Your correspondent "Success" seems to think our "high-toned" professors make money a trivial consideration in their calling; but I am constrained to think that the making of money is the first and last consideration with them when I look at the competition between our numerous colleges and the persuasive inducements they advertise in the daily press and elsewhere to win students; for if professors secure large classes, fame and remunerating consultations follow. But if money is such a trivial consideration with these "high-toned" gentlemen, why do they practise extortion on our patients when they consult them. Their consideration for the dignity and welfare of the profession outside of themselves is more a myth than a fact, and the colleges of these "high-toned" professors are as much a pecuniary speculation as some other money-making enterprises that they may affect to look down on. If they are really "high-toned" gentlemen, they must look with sadness at the crowds of poor students that are flattered into spending their money and time on a profession that must eventually fail them; and if young men do not wish to "suffer the slings and arrows of outrageous fortune," while waiting for practice, they had better spend their money and time in business that will be more speedily remunerative. We have had enough of the high-tone and dignity sham, and now let us have the facts—the facts

that colleges and hospitals are run for the fame and pecuniary profit of a few medical men who are to a great degree regardless of the rights of our profession.

September 27, 1875.

SUCCESSFUL PRACTITIONER.

MEDICAL APPOINTMENTS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—The recent discussion in THE MEDICAL RECORD of the "Presbyterian Hospital Affair" has led me to make some investigations into the statistics of the medical appointments in our charitable institutions, with a view to determine, in some degree at least, how much of truth there might be in the charge that these positions can only be obtained through favoritism and the influence of cliques. I send you the results of my somewhat laborious task, which you are at liberty to publish if you think they are likely to prove of sufficient interest to your readers.

The medical cliques in New York are numerous, as every practitioner very well knows, and it would be impossible for one observer to trace them all out, even though he might have abundant time and opportunity. I therefore selected the medical colleges of the city to represent the clique interest, and took for my guides the annual catalogues of these institutions, and the last number of the *Medical Register*. I do not claim to have reached absolute accuracy in my results, but I believe them to be sufficiently correct to indicate quite nearly the points which I set out to determine. So far as figures go, I have tried to be entirely accurate, but college influence makes itself felt in the case of many physicians whose names do not appear in the catalogues, and a statistical summary of course can take no count of these.

The total number of physicians in New York, according to the *Medical Register*, is 1,197, and the total number of positions to be filled by medical men in the benevolent associations, asylums, hospitals, dispensaries, and infirmaries amounts to 754; 205 being consulting and 549 active.

These 754 positions are filled by 410 doctors, 100 of whom are directly connected with the colleges, and 310 are independent of the colleges.

The 100 college men fill 306 positions; 146 being consulting and 160 active.

The 310 independent men occupy 448 positions; 59 being consulting and 389 active.

- 1 college physician holds 11 positions.
- 2 college physicians, each holds 10 positions.
- 3 college physicians, each holds 9 positions.
- 2 college physicians, each holds 8 positions.
- 1 college physician, and 1 independent physician, each hold 7 positions.
- 6 college physicians and 1 independent physician, each holds 6 positions.
- 8 college physicians and 2 independent physicians, each holds 5 positions.
- 7 college physicians and 6 independent physicians, each holds 4 positions.
- 12 college physicians and 19 independent physicians, each holds 3 positions.
- 27 college physicians and 63 independent physicians, each holds 2 positions.
- 31 college physicians and 218 independent physicians, each holds 1 position.

F.

DUCHENNE, OF BOULOGNE, the well-known author of works on paralysis and electricity, is said to be severely ill.

LIGATION OF FUNIS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Dr. Geo. Bayles says, in his article on "Elastic Ligature for Securing the Funis," in No. 251 of MEDICAL RECORD: "Another ring is commonly slipped over the placental end of the funis," and Dr. E. R. Pulling, in his article in MEDICAL RECORD, No. 245, "One (clamp) being used to apply temporarily to the placental end of the funis."

The small quantity of blood which flows through the placental extremity of the cord, as soon as the latter is divided, does not come from the maternal system—according to our knowledge of anatomy and physiology of the placenta—it is only the disengagement of the umbilical arteries and vein, which vessels ramify on the fetal portion of the placenta. This very disengagement is certainly harmless to the mother, and as it is generally believed that it facilitates the delivery of the placenta, it has been recommended to use *only one, and not two ligatures.*

Respectfully,

A. ROSE, M.D.

266 SEVENTH STREET, NEW YORK, August 28, 1875.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Sept. 26th, 1875, to Oct. 2d, 1875.

McPARLIN, T. A., Surgeon.—Assigned to duty as Chief Medical Officer of the District of New Mexico. S. O. 182, Dep't of the Missouri, Sept. 28, 1875.

WRIGHT, J. P., Surgeon.—When relieved by Surgeon McParlin, assigned to duty at Fort Leavenworth, Kans. S. O. 182, c. s., Dep't of the Missouri.

TAYLOR, B. D., Assistant Surgeon.—Assigned to duty at Fort Rice, D. T. S. O. 187, Dep't of Dakota, Sept. 25, 1875.

WOOD, M. W., Assistant Surgeon.—Assigned to duty at Camp Sheridan, Neb. S. O. 105, Dep't of the Platte, Sept. 25, 1875.

WEEDS, JAMES F., Surgeon.—Died at Nashville, Tenn., Oct. 1st, 1875.

NAVY.

October 3.

DUNGAN, JACOB S., Medical Inspector.—Ordered to the *Brooklyn*, as the Fleet Surgeon of the South Atlantic Station, per steamer of the 23d inst. from Baltimore.

LEACH, THOMAS W., Medical Inspector.—Ordered to duty as a member of the Naval Medical Examining Board at Washington, D. C.

JACKSON, SAMUEL, Medical Inspector.—Detached from the Naval Hospital at Norfolk and ordered to the Naval Hospital at Chelsea, Mass.

MARTIN, CHARLES, Medical Director.—Detached from the Naval Hospital at Washington and ordered to the Naval Hospital at Norfolk, Va.

GRINNELL, F. M., Medical Director.—Detached from duty as a member of the Medical Examining Board, and ordered to the Naval Hospital at Washington.

BULL, J. W., Assistant Surgeon.—Detached from the *Minnesota*, and granted four months' leave.

Medical Items and News.

THE LATE DR. E. KRACKOWIZER.—The Medical Board of Mount Sinai Hospital met at the residence of the president, Dr. Willard Parker, 41 East 12th street, New York, October 1st, 1875, when the following report was read and adopted:

The Medical Board of Mount Sinai Hospital meet to-night for the purpose of giving expression to their deep sorrow at the death of Dr. Ernst Krackowizer. A few resolutions of any nature whatsoever would not suffice to do justice to the memory of one on whom the most erudite and experienced surgeons of the country looked as their equal; who was recognized as a superior pathologist by the foremost men of the American profession; admired and called in council by all for his learning, skill, sound judgment, philosophical profoundness, and urbanity of manner; whose only ambition was incorruptible probity for himself and the elevation of the profession and mankind in general, and who, therefore, participated and led in every effort—professional, social, and political—in behalf of his exalted views and aims. In their prosecution he spent his strength and health, equally with his means, while his generosity was surpassed only by his modesty.

When such a man is removed from his sphere of usefulness, the universal feeling is that of a universal calamity. As his immediate colleagues, however, we deem it proper to simply express the deep sense of our bereavement. The Mount Sinai Hospital loses in Dr. Krackowizer a most zealous and successful surgeon and counsellor, whose services have been of invaluable importance to the Hospital. Both the Medical Board and the suffering sick will always remember them with both gratitude and sadness; and therefore the Medical Board, knowing what they have lost themselves, avail themselves of this sad opportunity to express to the family of the deceased their heartfelt sympathy with their loss, which cannot possibly be either repaired or forgotten.

A. JACOB, *Chairman.*

THE "ORDER OF LECTURES."—The *Boston Medical and Surgical Journal*, referring to the Order of Lectures recently published by us, says: "We do not know how accurate it may be in other respects, but we happen to know that the order of exercises at Harvard has not yet been determined"—rather an ill-natured observation when we consider that the information we gave was received direct from the secretaries of the respective schools, Harvard included, and that the writer of the article in the *Journal* could specify no inaccuracy. We won't tell the little story about the "mote in thy brother's eye," but will ask the editors of the *Journal* to take another look at the first line of their article and observe the beam in their own eye.

THE CODE OF ETHICS OF THE AMERICAN MEDICAL ASSOCIATION has been unanimously adopted by the Medical Society of Munich, and translated for the use of its members, bearing, in German, the title *Der Aertzliche Stand und das Publikum. Eine Darlegung der beiderseitigen und gegenseitigen Pflichten.*

DR. F. W. HEADLAND, of London, author of the Fothergill Prize Essay in 1852, on the Action of Medicines in the System, died recently in that city, at the age of forty-six. Of late years he devoted quite as much time to political journalism as to the practice of his profession, and was but little connected with medical affairs or societies.

REMARKABLE POST-HUMAL PRESERVATION.—At Greenwich, England, the bodies of some children were exhumed after thirty years' burial, and it was found that everything connected with them was in as good a state of preservation as when committed to the earth. The brass nails and coffins were bright and fresh, and the embroidery on the dresses as unruffled as if it had just left the dressmaker's hand. The infants themselves—to use the words of an eye-witness—were as perfect as if they had just been born. The cause for this singular preservation is not understood.

THE CHOLERA IN SYRIA.—The correspondent of the *British Medical Journal* writes from Constantinople that the cholera seems to be declining in all the Syrian towns with the exception of Aleppo, where, during the week ending August 15th, there were three hundred and forty-one cases, and two hundred and fifty-three deaths. At Damascus, from the 9th to the 11th, there were only nine new cases.

NEW MEMBERS OF THE RESIDENT STAFFS OF HOSPITALS.—The following-named gentlemen were successful in the recent examinations to fill the October vacancies in Bellevue and Charity Hospitals: *Bellevue*, Drs. Heimmuller, Pell, Stilwell, Peck, Woodruff, Simonson, Norris, and Kalish. *Charity*, Drs. Knight, Knickerbocker, Linchan, Oppenheimer, Ruccavado, Myers, and Hoffman.

THE HOSPITAL SUNDAY FUND collected in the London churches amounted this year to £26,703, against £29,817 received last year. It is to be distributed among one hundred and twenty-two institutions of different sorts embraced under the term "hospital."

PROFESSOR DEPAUL.—It is reported that Professor Depaul, of Paris, has been invited to Brazil, to assist the daughter-in-law of the Emperor in her approaching confinement. His fee is to be \$50,000, with \$10,000 for his expenses.

A STATUE OF SUTIN, one of the most noted of Belgian surgeons, has recently been erected in the court of the Hospital Saint Pierre, at Brussels.

NOVELTIES IN VETERINARY PRACTICE.—*The Lancet* says that a cow on the farm of a Mr. Wilson, at Burrowdale, in Cumberland, suffered a fracture of the leg for which amputation became necessary. The stump healed well, and a wooden substitute for the part removed was adjusted, and the animal was enabled to walk about and feed in pasture.

The *Lyon Medical* adds to this the statement that Prof. Hertwig has employed artificial eyes of hard rubber to replace the organ when lost by horses. Not only do they prevent the entrance of dust and insects into the cavity of the orbit, but they add to the appearance of the animal. The operation for their introduction is very simple, and they require to be cleaned only about once a week.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

[THE MEDICAL RECORD is published every Saturday. Notices of meetings, lectures, operations, etc., intended for publication in this bulletin should be received at the office, 27 Great Jones Street, one week previous, to insure their appearance.]

Tuesday, Oct. 12th.—Med. Soc. of the County of N. Y. (adjourned meeting), at the Col. of Phys. and Surg., 23d st., cor. Fourth av. "The Genesis of an Epidemic of Puerperal Fever," William T. Lusk.

Wednesday, Oct. 13th.—N. Y. Pathological Society, Col. of Phys. and Surg., 23d st., cor. Fourth av.

Friday, Oct. 15th.—Med. Library and Journal Assoc., 107 E. 28th st. "On Apoplexy," by John C. Peters.

Original Communications.

HOUSE SEWERAGE.

A REMARKABLE GROUP OF DISORDERS IN ONE FAMILY, THE RESULT APPARENTLY OF A DEFECT IN DRAIN PIPE.

By JAS. D. TRASK, M.D.,

ASTORIA, L. I.

Oct. 23d, 1873, I attended Mrs. A. B., in her sixth confinement. The house then occupied by the family is but a few years built, and contains the ordinary modern conveniences. Mrs. B.'s convalescence from her confinement had been unusually slow, which was attributed to her previously delicate health, when on the sixteenth day from delivery she was suddenly seized with symptoms of acute peritonitis. The fever was high, pain excruciating, tenderness extreme, and there was frequent vomiting. Large and frequent doses of morphine were required to subdue the pain, producing at times deep narcotism.

After five days the severity of the symptoms abated. There was still great tenderness and tympanites for a week or more following, with irritable stomach and great muscular prostration. On the 25th of November the acute symptoms broke out again with almost their original severity. From this time onward, throughout the month of December, there were periodical exacerbations or relapses, of which she had five very distinctly marked. The earlier attacks were regarded as peritonitis. Quinine was given in large doses from the first, the patient being unusually tolerant of it, and such nourishment as could be borne; but in a short time nothing but small quantities of liquid diet could be retained.

In the early part of December she was seen by my friend Fordyce Barker, who expressed the opinion that, whatever might have been the nature of the original attack, the present existing pain was to be regarded as caused by neuralgia of the peritoneum. Dr. B. advised pushing the quinine to the extent of producing its full physiological effects. After the 1st of January Mrs. B. gradually convalesced, and was able, by the 21st of February, to sail for Florida.

On the same day on which the mother was taken ill, as above described, her oldest son, who had been sent to the house of a relative, was taken with symptoms of fever of a continued type, which soon became severe. There was great prostration, no decided diarrhœa, no rose-spots. The sickness continued four weeks.

One week from the seizure of the mother and son, the cook, a woman of about sixty years of age, was taken down with a fever similar to that of the son, accompanied by rose-spots and diarrhœa, of which she eventually recovered.

On the same day the wet-nurse of the infant took her bed with what, after her subsequent removal to St. Vincent's Hospital, turned out to be cerebro spinal meningitis, of which she recovered.

One week after this two more of the children, who had been kept away from the house for at least three weeks, were seized with symptoms like those of the first child, and were sick for about three weeks. The infant died when three weeks old, but from causes disconnected with the house chiefly.

Of the remaining members of the family, the youngest child, but a little over one year old, who was retained at home with its nurse, suffered also from

serious gastric disturbance, with marked general depression, and slight febrile excitement. Of a family of ten, only the nurse of the young child and the husband escaped illness in some form during the time of the protracted sickness of the mother.

Immediately upon the occurrence of the illness of the cook and wet-nurse, in connection with that of the mother and son, the conviction was forced upon the mind that there must be a common origin for all the attacks. Inquiry revealed the fact that at times unpleasant odors had been recognized in the parlors, especially in the vicinity of the folding-doors. Carpenters had already been employed to ascertain the source of this, and plumbers had examined the waste pipes and reported every thing unimpeachable. It was now resolved that a thorough overhauling of the premises should be instituted. This was made by those regarded as competent, and nothing out of the way found. The more the subject was reflected upon, the more confirmed became the conviction that the evil was in connection with the waste-pipe, at some point that had as yet eluded discovery. At length, after days had been spent in fruitless search, under the belief that Mrs. B. could not recover so long as the atmosphere of the house was poisoned, I insisted upon such an examination as should settle the point in dispute, and at last the source of the escape of the mephitic gases was discovered in an imperfect joint, just at the point at which the pipe was about to pass under the cellar wall into the main sewer; this leak being so situated as to allow the gases to pass up directly through the space between the plastering and the wall, and from thence by free communication into the parlors, through the casings of the folding-doors. It was not until near the end of December that the *fons et origo* of all this evil was discovered.

This narrative I regard as highly instructive, as illustrating the influence of sewer gas in producing disease, and also the difficulties that beset all such examinations, mainly in consequence of the gross incompetence of mechanics whom we are compelled to employ.

But the interest of this recital does not cease here. In the spring of the same year the family of Mr. B. removed to another house. The children, who had been previously delicate, and especially prone to gastric derangements, have since enjoyed perfect health. The health of Mrs. B. has remained delicate in consequence of chronic endometritis. On the 16th of January, 1875, she was seized with a sharp attack of metritis a few days subsequent to the menstrual period, which lasted a week, and on the 14th of February, at a corresponding date, there occurred a well-developed attack of metro-peritonitis, but little inferior in severity to that occurring a little over a year before. From this attack she had a long and tedious convalescence. As she began to recover, it came to my knowledge that during the previous extremely cold weather the waste-pipe leading from the water-closet adjoining her sleeping-room had, a few days before, been found completely blocked up by ice. There is no doubt that this accident occurred early, and that the atmosphere of this lady's apartment had been contaminated for some weeks by noxious exhalations unperceived by the senses.

Doubtless, in this particular instance a peculiar susceptibility to such influences may exist; but it does not seem to me to admit of any reasonable question that the attacks here described were due to the direct action of the poisonous exhalations from the obstructed drains. If the uterus may be the subject of congestive hypertrophy that can be measured by the sound, under

the action of malaria, I see no reason why it may not, with its investing peritoneum, become the subject of inflammation from the exhalations of defective drains. In the present instance the convalescence of Mrs. B. was characterized by acute neuralgic pains, apparently located in the peritoneum.

It is not many years since the wife of a well-known professional gentleman of New York died under my care. She had acute metritis, coming on with no exciting cause, so far as could then be ascertained; but from the first there was a depression about her that was unaccountable. To myself, as well as to Dr. Barker, of New York, who saw her with me, her aspect and condition were suggestive of blood-poisoning. There was more or less evidence of the inflammation extending to the peritoneum also. After her decease I learned that the family, who had just removed for the summer from the city, had occupied one of a block of houses in a fashionable part of the city. The street sewer opened into the North River, above low-water mark, and consequently when the wind blew from a westerly quarter, at low tide, the poisonous gases were driven back, and diffused throughout the interior of dwellings connected with it by drains. This had often been a subject of observation in the neighborhood, as well as in the house in which this family resided, and there is no doubt that here was the direct cause of the deadly attack in the instance referred to.

This and the preceding case seem to show conclusively that metritis and metro-peritonitis may directly result from poisoning of the atmosphere by sewer gas, while the first case illustrates the variety of disorders that may be simultaneously excited in different members of a family by this cause.

The extreme difficulty at times of demonstrating the source of these exhalations, even when recognized as offensive, and especially when only suspected, ought to be impressed upon the mind of every practitioner. This arises mainly from the shameful incompetency of most workmen upon whom we are obliged to depend. As an instance of this, in a certain dwelling-house, with "modern conveniences," the family for years past have suffered annoyance from what was regarded as "rats in the wall." Much money and labor had been expended in tearing up floors and breaking through walls. In the meantime one member of the family died of a fever, which conformed to no particular type, but was characterized by typhoidal depression. During the last year my attention was called to these facts, and I insisted upon a new and thorough examination of the drain-pipes, and of the soil in their vicinity. This was done in an apparently thorough manner by men regarded as competent, but the evil continued. In the hall and certain rooms the atmosphere was often oppressively offensive. Quite recently the house, on passing into the hands of a new party, has been thoroughly overhauled, and new drain-pipes introduced. During the progress of this work the original drain-pipe was found to have parted just under the wall of the cellar, and thus free access of the gases was permitted to the entire space between the plastering and wall of the house.

I have known several instances in which, from the overflow of cess-pools, and sometimes from the deliberate act of indolent and unprincipled domestics, the soil beneath the floor of the kitchen or laundry has become saturated with drain-water. In one instance in which this had occurred, there were two deaths from fever of a typhoid character, and such fevers are of extremely rare occurrence in this vicinity.

It is plainly the duty of the family physician, as oc-

casions offers, to remind those under his charge of this deceitful source of disease, and of the necessity of personal watchfulness over the sanitary condition of their homes.

In this connection it is of interest to note that diphtheria is now prevailing in this immediate vicinity, and has proved very fatal, and that, so far as can be ascertained, it is confined almost entirely to two streets, in which the gutters are notoriously filthy, and that not a case has thus far occurred on the streets in which attention is paid to cleanliness.

CLINICAL NOTES ON INCARCERATED HERNIA,

AND OF THE VALUE OF THE ASPIRATOR IN THEIR TREATMENT.

By EUGÈNE PEUGNET, M.D.,

FORDHAM HEIGHTS, NEW YORK.

It is a well-known fact that the incarceration of a hernia is due either to a constriction at the neck, external to, or within the sac itself; also to over-distention of the sac by serous effusion within it; again, by distention of the intestine, without there being any *primary* constriction at the neck.

The advice given by most of the skilful operators is first to divide the constriction externally to the sac, in case there should be any; then, if that fails, to open the sac, although we must always be guided by the duration of the strangulation and the urgency of the symptoms, as by thus reducing a hernia without exposing the intestine we might reduce one in a gangrenous condition. The above is no doubt in a measure orthodox, but many distinguished authorities, among others Sir J. Paget, appear to have overlooked the fact that over-distention of the sac by serous effusion is frequently, *secondarily, it is true*, the essential cause of the incarceration. Most of them refer to the distention of the intestinal tube. Mr. Thomas Bryant found it necessary to puncture the intestine, which had again protruded, subsequent to herniotomy with exposure of the intestines, and this after the constriction at the internal ring had been freely divided. His success in this case thus led him to propound the following axiom: "If, after operating, we can reduce a strangulated hernia by pricking, which we could not reduce without, is it not possible that we might reduce some hernias without any operation at all?" Dr. Leon Labbe thus reports its successful application by means of the aspirator in a case of inguinal hernia: "Taking into account the circumstance that the strangulation dated only about eighteen hours, and that probably the anatomical changes would be very slightly advanced, I, without hesitation, proposed puncture with the aspirator, and without further delay I introduced the No. 2 needle. About 10 grammes (two drachms and a half) of a yellowish liquid immediately escaped, together with a quantity of gas, which I cannot exactly estimate. The tumor, which was as large as a fist, flattened immediately, and a very gentle pressure exerted for one minute at the neck of the sac caused complete reduction of the hernia."

My attention was first called to this cause of incarceration by a case, also seen by Dr. Varian, of incarcerated congenital inguinal hernia, in a boy aged 4 months and 20 days, which gave rise to convulsions. On exposing the sac and puncturing it, the intestine immediately receded. The second was that of a farmer, 30 years of age, a patient of the late Dr.

Stone, of West Farms, with inguinal hernia of right side, which had been incarcerated for 72 hours. As the symptoms of strangulation were urgent, I opened the sac, which was very much distended with serum; as the intestine had undergone no marked change, I returned it without difficulty or any division at the neck, either within or without. The third was that of a man, 77 years of age, on whom I operated, with the assistance of Dr. Horsefield, with an inguinal hernia of 23 years' standing, which had become irreducible sixty hours previously, the only occasion in which the patient had failed to reduce it. The enormously distended sac was opened, a large quantity of bloody serum escaped, clots of blood then removed from the surface of the intestine, and the latter readily reduced. This man is now 87 years of age. All made a good recovery.

The first opportunity presenting itself for the practical application of the principles thus inculcated was a case of inguinal hernia of left side, in which the testicle had never distended into the scrotum. The subject, a man 55 years of age, had been suffering from it since boyhood, and on the 10th of May, 1875, the hernia protruded; the pressure of the pad had caused an inflammatory action in the sac, which rendered it exquisitely painful and sensitive. Having anesthetized him, both Dr. C. M. Kellogg and I failed to reduce it. Then, with the concurrence of the Dr., I introduced the No. 2 needle of the aspirator into the tumor, which was about the size of the fist, at its upper and external angle, horizontally downwards, thus removing four ounces of serum from the sac. The loop of intestine and the testicle could then be distinctly felt through the parietes. As there had been no symptoms of strangulation no further attempt at reduction was made, but hot fomentations applied, and twenty grains of calomel administered; within ten hours the hernia was spontaneously reduced. At first I thought the intestine had been punctured, as a quantity of air bulbs passed into the aspirator, but subsequently ascertained that it was due to a slight defect in the aspirating tube.

The second, that of a widow, a patient of Dr. De Marmion, with a femoral hernia of the right side, which had been down for four days, all attempts at reduction having failed, and nausea with vomiting having occurred. With the concurrence and assistance of Drs. Naudain, Comfort, and Joyce, I performed the usual operation, dividing Hey's ligament, which relieved the external strangulation, but still the hernia remained irreducible. I accordingly raised the sac, and depressed the intestine, whilst Dr. Joyce introduced the aspirating needle, thus permitting the escape of clear serum; the intestine was then readily reduced. The patient had a profuse evacuation immediately after the reduction, and thirteen during the night. On the second day an unusual phenomenon manifested itself; the distended sac protruded through the lower segment of the wound, but as it evidently contained no intestine, it was left alone, especially as symptoms of phlegmonous inflammation had manifested themselves. The patient made a good recovery, and is now perfectly well.

The above-mentioned cases demonstrate the value of the aspirator in over-distention of the sac. But I have within a year operated on two cases of femoral hernia in which its use would have been entirely inadvisable. The first, on the 30th of November, 1874, was on a married woman, 30 years of age, who had a femoral hernia of five months' standing, which her husband was even unaware of. She sent for me, thinking that she was about having a miscarriage. I in-

sisted upon making an examination, and discovered this hernia. Although symptoms of peritonitis had manifested themselves, with the concurrence of Dr. Bathgate I proceeded to operate, as a *dernier ressort*. The sac was inflamed, and the intestine, although dark-colored, reduced; but the patient died thirty hours after. No post-mortem allowed. On the 24th of June, 1875, I operated on the second one, a patient of Dr. Elting, a man 82 years of age, who had had for a number of years a hard kernel in right femoral region. On the 22d, whilst standing on a ladder, attempting to pick cherries, he strained himself. On the 23d, Dr. Elting being sent for, recognized the difficulty. On the 24th, while the patient was etherized, Drs. Comfort, Horton, and Elting fruitlessly endeavored to effect a reduction. I saw him at 9 o'clock in the evening. He had incessant hiccup, vomiting, a cold, clammy sweat, and a pulse of 120. The usual operation exposing the sac, then opening it, was performed. The intestine, although chocolate-colored, was readily reduced, leaving the above-mentioned hard kernel, which proved to be a portion of the omentum; this was readily reduced after separating a few adhesions. This patient made a rapid recovery, and is now quite well.

It is therefore evident that the *aspiration, or the puncture*, are only of value in those cases in which the sac is fully distended by its contents, either from serous effusion or owing to a distended intestine. But even then we should make no attempt at reduction by such means, if the symptoms of strangulation are marked, and have been prolonged, as, although their application might prove successful, it would in all probability be prejudicial, as we might thus reduce an intestine in a gangrenous condition, which would then indeed prove to be malpractice.

CASE OF GONORRHOEAL EPIDIDYMITIS OCCURRING BEFORE THE APPEARANCE OF THE DISCHARGE.

By FRED. R. STURGIS, M.D.

CLINICAL LECTURER ON VENEREAL DISEASES IN THE UNIVERSITY OF THE CITY OF NEW YORK (MED. DEPT.), ETC., ETC.

THE notes of the case, for which I am indebted to the kindness of Dr. E. T. Ely, of this city, are as follows:

A. L. B., a gymnast, æt. 19, of general good health, and free from all previous venereal disease, came under observation with the following history: On April 6, 1875, he had connection with a woman of the town; he suspects she had a discharge from the genitals, but is not positive of it. Between the 6th and 15th inst. he had intercourse twice with his wife; the last time on the 13th. He is quite positive his wife has no discharge. On the 15th April, he had a chill, followed by fever and malaise, accompanied by a severe pain in the hypogastrium and in the left groin, and thinks he passed bloody urine. Supposed he had "taken cold," as he had been sleeping near an open window. The next day (16th), he noticed that the serotum was red, and the left testicle swollen and tender; the pain in the groin had somewhat moderated. These symptoms remained in *statu quo* until the 19th, when he was seen for the first time. He then had well-marked epididymitis of the left side, with considerable fever. Temp. 102°. *No trace of any urethral discharge could be detected, and he is certain that there has been none.* He has had no pain in passing water. Is positive that he has sustained no injury or strain. Has had no treatment beyond a poultice

applied over the hypogastrium. Rest in bed, saline cathartics, and a suspensory bandage were advised.

April 20th.—Admitted to hospital. No change in the symptoms. *No evidence of a urethral discharge.* Testicle supported on a pillow, and a lead and opium wash applied to the gland. E. temp. 102°.

21st.—First noticed scalding during micturition last night. *This morning there is a scanty but thick purulent discharge from the urethra.* Was ordered Lafayette's mixture* internally three times daily, and an injection of cupri sulph., gr. ii. in aq. $\frac{3}{4}$ i. every four hours. M. temp. 99°. E. temp. 103.

22d.—Discharge free and purulent; micturition quite painful; testicle about the same; no marked pain, except on pressure. M. temp. 101°. E. temp. 101.5°.

23d.—Less discharge, and less pain in urinating. M. temp. 99.8°. E. temp. 100°.

25th.—Discharge almost ceased. A drop of thin fluid can be squeezed from the meatus by pressure along the urethra. Inflammation of the testicle subsiding. Temp. normal.

27th.—No discharge seen yesterday or to-day. Testicle better, but epididymis considerably indurated. Testis strapped. Lafayette's mixture discontinued.

May 1st, 1875.—Discharged from the hospital at his own request. Considerable induration and enlargement of the epididymis still remaining. No urethral discharge can be detected. Injection stopped.

May 4th.—Came as out-patient. Testicle improved. Urethral discharge reappeared yesterday, thin and white in character. Patient denies having committed any excess. To inject a two-grain solution of nitrate of silver three times daily.

Patient has not been seen since.

NOTE.—The case is of interest from the fact that the epididymitis preceded the urethral discharge by fifteen days, instead of occurring, as it usually does, between the third and eighth week, from the beginning of the disease. The objection which might be raised, viz., that the discharge may have existed prior to the inflammation of the testicle is, I think, easily disposed of. Were the patient's word the only evidence, it might be a question; but from the 19th inst. until the 21st, when the discharge appeared, he was under medical observation, and it is specially mentioned that none was evident. But few such cases are recorded in medical literature, only two being, so far as I know, on record; one by Castelnau, where the running occurred five days after the urethral discharge; and the other by Vidal.† Here three times the length of time elapsed. It is always possible that the whole trouble may have been catarrhal, due perhaps to the sleeping near the open window, and this is allowable, so long as we have no positive evidence of gonorrhœa in the woman. Be that as it may, the case is a curious one, and shows that in very rare cases the testicle may be affected before any evidence of urethral trouble is apparent.

A CASE OF

“PARTIAL PARALYSIS FROM REFLEX ACTION CAUSED BY ADHERENT PREPUCE.”

By J. H. HUNT, M.D.,

PORT JERVIS, N. Y.

(Abstract of history read before the Tri-States' Medical Association.)

THE history of the following case, as it appears in my case-book, possesses considerable interest, especially as it represents a typical case of the disease, “Reflex Genital Irritation,” first described by Dr. Lewis A. Sayre, in 1870, before the American Medical Association. Dr. Sayre more recently read an elaborate paper at the last meeting of the American Medical Association, at which time cases were narrated as occurring in both sexes.

Samuel Moore, at. six years. The patient was injured May 24th, 1875, by the wheels of a wagon, heavily loaded with stone, passing over both lower extremities. There was found a compound comminuted fracture of tibia and fibula of right, and a simple fracture fibula of left leg. In right limb the fracture of tibia was situated at junction of middle with lower third, while the adjacent bone was fractured somewhat lower. The wound was longitudinal, three and a half inches in length, and situated on upper and inner surface. In the left leg, the fracture was found to be situated at a point two inches above malleolus. The limb was very much swollen and contused. The fractured members were placed in fracture-boxes, and evaporating lotions applied. On the following day it became evident that, owing to extreme restlessness and nervousness on the part of the patient, other measures would have to be adopted to retain the fractured bones in position. A plaster-of-Paris splint was at once applied to fracture of right side, a fenestra cut opposite the wound, and the leg supported in a modification of Dr. Van Wagenen's apparatus. The fracture of left leg was treated by placing it in a wire fracture-splint, properly padded, and applying evaporating lotion. The patient made a rapid recovery. During convalescence, I frequently noticed the penis in an erected state. On examining the organ the prepuce was found firmly adherent by its entire circumference to the glands, at a point midway between corona and meatus. Margin of meatus red, and presenting granulations. On interrogating the mother the following facts were elicited. The child, since learning to walk, had a peculiar staggering gait; seemed unable to properly control the lower extremities. He very frequently fell down without sufficient cause. He was exceedingly nervous, and affected with twitchings of muscles of face and extremities. Had a habit of suddenly plunging the right hand into breeches-pocket, without apparent reason, then quickly withdrawing it. Whenever the genitals were exposed to her view, the penis was invariably in an erected state. The child was in the habit of starting, and screaming out during sleep. When asked to protrude the tongue, an effort would be made, but the organ usually rolled about in the mouth, without protrusion being effected. The child was unable to articulate well, and the intellectual faculties, so far as could be observed, were below the average.

A loquacious neighbor informed me that the child, because of its idiocy, were “better dead than alive,” and that it was a curse to the family, and a subject of ridicule by the neighbors, because of the supposition that the child was marked in utero, from the mother seeing the father in an inebriated condition.

When the patient had partially recovered from his injuries, or about three weeks after receiving them, I performed circumcision in the usual way. The wound soon healed, leaving the prepuce sufficiently long to allow it to be drawn over the glands. Almost immediately improvement became manifest, and although only eleven weeks have elapsed, the boy has completely recovered from his infirmity. The gait has lost its staggering character, and the tendency to tumble down has disappeared. The convulsive twitching are no longer observed. Can protrude the tongue without difficulty; mental faculties are decidedly improved; sleep undisturbed; while the erections of the penis have lost their abnormal frequency.

PORT JERVIS, N. Y., September 13th, 1875.

Progress of Medical Science.

CASE OF PULMONARY AND TRICUSPID VALVULAR DISEASE.—Mr. Alexander Morison, of London, reports the case of a youth, aged 20, who had scarlatina at five years of age, and who was known to have had heart disease at eight years of age. His family history on both sides was rheumatic, cardiac, and phthisical. Till eighteen he performed clerk work satisfactorily, when exercise at cricket seemed to bring on his urgent heart symptoms. The pulse varied from 78 to 84, regular, small, but distinct. There were pulsations in the suprasternal fossa, with regurgitation into the external jugulars; the carotids were normal. There was a bulging forward in the precordial region, flattening under the left clavicle, visible systolic pulsation from the second left intercostal space to below the nipple, well-marked epigastric pulsation, increase of the transverse heart dulness. A systolic bruit was heard at the left edge of the sternum, below and to the inner side of the nipple, not traceable round the left chest. There was a double murmur, best heard over the third left cartilage, harsh and grating, not propagated into the large arteries, but towards the left shoulder. He had angina passing to the right shoulder and down the right arm. The breathing was harsh; no marked dulness, and no crepitation. The liver was enlarged; some albuminuria was present; the bowels were regular, though latterly he had had some diarrhoea. Some purpura was present. He died without convulsions. At the post-mortem examination there was found valvular obstruction at, and regurgitation through, the pulmonary and tricuspid valves, which were much altered by warty vegetations. The tricuspid obstruction was not so pronounced as the other conditions. The right ventricle and auricle were dilated, the latter somewhat hypertrophied. A partially defibrinated clot was found in the auriculo-ventricular orifice, and another passing through the pulmonary opening, and stretching into the two chief bifurcations of the pulmonary artery. The mitral and aortic valves were healthy, though there was some deposit on the mitral segments. The left ventricle was not hypertrophied. The muscular fibres were healthy. The lungs were small, crepitating, but with scattered patches of induration; both extreme bases were solid. The kidneys were much engorged.

Mr. Morison ascribed the valve lesions to scarlatinal endocarditis, and considered the kidney affection as more recent than the heart disease.—*Trans. Brit. Med. Ass.*—*British Med. Journal*, August 21, 1875.

SPENCE ON LISTER'S ANTISEPTIC METHODS.—At the late meeting of the British Medical Association Prof. Spence introduced a number of facts going to show that Lister's treatment was not the only one that gave excellent results in surgery. Suppuration, he believed, was not unknown in this antiseptic system, whilst the average duration of treatment, as far as he could learn by hospital statistics, was not lessened.

As an instance of another method he stated that during three years, out of sixty-three major amputations for disease, he had had three deaths; and out of twenty-three cases of excision of joints only two deaths. His treatment consisted in thoroughly washing the surface of the wound by pouring tepid water over it, occasionally applying tincture of iodine to the flaps, while the dressing consisted of a fold of lint or thin muslin. In preparing his statistics of amputations he found that the nature of the disease or injury had a very important influence on the result. In the treatment of wounds all surgeons had for their object the avoidance of putrescence, though their views might differ as to the best way of attaining it. In treating lacerated wounds and burns of the extremities he recommended continuous immersion in the tepid bath, and here the antiseptic method could be carried out most thoroughly by mixing carbolic acid with the fluid.—*Medical Press and Circular*, Aug. 18, 1875.

NATURAL HISTORY OF DYSENTERY.—In 1853 Dr. Austin Flint published a clinical report of dysentery, based on an analysis of 49 cases. From data obtained in these cases Dr. F. drew certain conclusions with regard to the nature of the disease, its etiology, duration, tendency to relapse or recurrence, fatality, etc. Briefly, dysentery was inferred to be an infectious disease, which "by preference" affected "persons in good health," in a salubrious northern climate rarely ended fatally after infantile life, and was neither disposed to relapse nor to recur in the same individual, or to become chronic. Thirty of the cases ended in recovery. Their duration varied from one to twenty-one days; reckoning from the date when diarrhoea commenced the mean duration was 9½ days. The above cases were variously treated—with laxatives, opiates, astringents, and topical applications in the form of enemata. Of all remedies opium was esteemed as the most valuable. The fact that different, and often opposite, methods of treatment have been employed with apparent success in dysentery is thought by the author to imply an intrinsic tendency in the disease to self-limitation. In order to ascertain the correctness of this inference, Dr. F. has recently supplemented the above analysis by the addition of ten cases of dysentery, in which the disease was suffered to pursue its natural course, without interference by medication. The ten cases were collected during the last three years, and were only selected with a view to a fair result. The history is presented in each case. All the cases ended in perfect recovery, and the mean duration was 11½ days, or, leaving out one case where a diarrhoea preceded the dysenteric discharges for 14 days, it was only 10½ days. Comparing the mean duration with that (9½ days) of the thirty cases ending in recovery in the previous analysis, the slight difference would imply that treatment had but little influence in shortening the duration of the disease. This influence is made to appear in a still more dubious light by comparing the cases which were treated in hospital with the ten which were left without treatment. Thirteen of the above 30 cases were treated in hospital, and their mean duration was 13 days, or three days longer than that

of the 10 cases not treated at all. Dr. F., however, deprecates drawing too strained an inference from this last comparison.

The writer closes with the following conclusions :

1. The disease, in a temperate latitude, tends, without treatment, to recovery.
2. It is a self-limited disease, and its duration is but little, if at all, abridged by methods of treatment now and heretofore in vogue.
3. Convalescence is as rapid when active measures of treatment have not been employed as in cases actively treated.
4. Relapses do not occur in the cases in which the disease has been allowed to pursue its own course without active treatment.
5. Sporadic dysentery, in a temperate climate, does not terminate in a chronic form of the disease; in other words, it does not lead to ulceration or other lesions of the mucous membrane of the large intestine, and it does not involve any tendency to complications or secondary affections.—*American Journal of the Medical Sciences*, July, 1875.

PROGRESSIVE MUSCULAR ATROPHY.—At a recent meeting of the Société Anatomique de Paris, M. Troisier presented the history of a case of progressive muscular atrophy, with autopsy. Clinically it was of the type described by Aran and Duchenne, and with M. Charcot might be termed the Aran-Duchenne type. The course had been exceptionally rapid (15 months). It was the fourth case published where the relation between the muscular atrophy and the lesion of the anterior horns had been demonstrated. The lesion of the anterior horns consisted in simple atrophy and in the disappearance of a large number of the nerve cells. There was no increase of the nuclei of the neuranglia; hence the atrophic process did not depend upon an inflammatory condition. The muscular atrophy was a simple atrophy, without granulo-fatty degeneration. This was invariably the case. A certain degree of interstitial lipomatosis, which always exists, may sometimes have produced the erroneous impression of a steatosis of the muscular fibre. There had been no increase of the nuclei of the sarcolemma, contrary to the observations of M. Hayem. The reason of this might have been that the case was of comparatively recent standing.—*Lyon Medical*, Aug. 15th, 1875.

GORRHOEAL RHEUMATISM.—M. H. Fourestié, an interne of the Paris hospitals, has collected 22 cases of rheumatism occurring in connection with gonorrhœa, with the view of showing a more definite relation between the two affections than has hitherto been established. The existence of a gonorrhœal rheumatism, properly so called, as a distinct and peculiar form of rheumatism, is by no means universally admitted. The coincidence is regarded by some as purely accidental, while others admit only so much as that in a rheumatic subject a urethritis may excite the arthritic tendency to an acute outbreak. Moreover, certain writers have asserted that only the acute form of gonorrhœa was capable of exciting the rheumatic attack. The object of Fourestié's researches was to show an intimate relation between the disease in the urethra and the rheumatic symptoms as regards their more or less acute or chronic character. Thus in 13 of the 22 cases an acute or subacute blennorrhœgia was found to coincide with an acute arthritis, or with an acute articular rheumatism affecting a number of joints. In four of the cases the same form of gonorrhœa was associated with simple rheumatic pains or with the apyretic form of polyarticular gonorrhœal rheumatism.

In four cases a chronic gonorrhœa gave rise to a form of rheumatism which differed from both the preceding forms. It was very long persistent, it affected only one or two articulations, showed a tendency to implicate the bursæ of tendons, causing a chronic inflammation of the adjacent cellular tissue, and was accompanied with acute pains, and often with pronounced anæmia.

In one case only the chronic blennorrhœa appeared to coincide with an acute polyarticular rheumatism. This case was regarded as exceptional.—*Gazette Médicale de Paris*, 27, 28, 32, 33, 1875.

TREATMENT OF CONDYLOMATA LATA.—The exuberant papular growths commonly known as flat condylomata, which sometimes occur in the neighborhood of the mucous orifices, particularly of the genitals, in syphilitic subjects, belong to the most repulsive and annoying of the manifestations of syphilis. Any mode of treatment by which their cure may be expedited must be esteemed as a desirable addition to our knowledge. Fournier advises in the way of local treatment simple attention to cleanliness and the application of some inert powder. In an article in the *Gazette Médicale de Paris* (July 31, 1875), Dr. Jules Charon claims that by more active measures the duration of the treatment may be decidedly abridged. He had formerly used the acid nitrate of mercury with which the papular growths were cauterized, and with much more rapid results than when Fournier's plan was pursued. But the object of the present article is to advocate the cauterization with nitrate of silver and metallic zinc in the manner first proposed by Professor Conradi. The method and its action are thus explained: When a portion of the integument is touched with a strong solution or the pure stick of nitrate of silver, the first effect is to produce a whitish or grayish discoloration, the whitish color being due to the formation of albuminate and chloride of silver. Gradually the spot assumes a darker color, becoming brown or chestnut colored, and finally quite black. The nitrate of silver is decomposed by the organic matter, and is after a time reduced to metallic silver, which uniting with the tissue causes the black color. If, while the reduction is in progress, two silver electrodes of a galvanometer are brought into contact with the spot to which the nitrate of silver has been applied, the passage of a slight electric current will manifest itself, the needle of the battery showing a deviation say of ten degrees. But a much more powerful action may be induced if metallic zinc is brought in contact with the spot after being touched with the nitrate of silver. The reduction of the silver, instead of taking a considerable length of time, is then affected immediately. If one of the electrodes of the galvanometer have a small rod of metallic zinc attached to it, as soon as the spot to which the nitrate of silver has been applied is touched with the zinc rod of the electrode, the black color is produced instantaneously, and the needle of the galvanometer shows a deviation of 45 degrees. The nitrate of silver thus aided by the zinc proves to be a very effective caustic, and for the treatment of the above syphilitic growths the writer has found it peculiarly serviceable. Tables of the series of cases of condylomata lata which were treated respectively by Fournier's method of simple attention to the ordinary rules of hygiene, by cauterizations with the acid nitrate of mercury, and with metallic zinc and nitrate of silver, are subjoined to the article, and show clearly the superiority of the treatment last named. Of 9 cases treated with simple cleanliness, inert powders, etc., the duration was 53-4

days; of 8 cases treated with the acid nitrate of mercury the duration was 29-30 days; 6 cases treated with nitrate of silver aided by metallic zinc were cured in 8-9 days.

ON THE TREATMENT OF CARBUNCULAR AFFECTIONS IN MEN AND ANIMALS.—At a meeting of the Académie des Sciences a report was furnished by M. Cezard, veterinary surgeon, on the treatment of carbuncular affections, that is, malignant pustule and its allied diseases, in men and animals. The following was the line of treatment suggested: First, to support the organism; and second, to neutralize the morbid effect of the poison. The one object might be accomplished by giving the acetate of ammonia internally, in doses varying from 50 to 200 grammes (an ounce and a half to six ounces nearly) in the twenty-four hours, and the other by the use of iodine, which he claims is the most powerful known remedy for destroying the morbid poison, even when the blood has become contaminated. In the proportion of 1 to 12,000, he says it will soon destroy the virulent power of a liquid outside the body; but when the system is infected it requires a comparatively smaller amount. Animals will support the introduction into the circulatory system of a quantity of iodine equivalent to more than $\frac{1}{20000}$ of the mass of the blood. Given by the mouth, or better, hypodermically, iodine is absorbed, and preserves its special properties even in the blood. In serious cases intra-venous injections may be practised. Iodurated fumigations are also beneficial. This general treatment is efficacious in the incubative period of malignant pustule and other allied diseases. Local treatment should be instituted as soon as possible, and the pustule should be treated both by subcutaneous injection and by wet applications of iodine, in a solution of 1 to 100. For animals this anti-virulent treatment is more useful as a preventive than curative; but as a prophylactic it is advised to use a solution of sulphuric acid (1-5000), which is to be sprinkled over the fodder or food.—*Recueil de Méd. Vétérinaire*.

ACUTE RHEUMATISM AND RHEUMATIC FEVER.—At the recent meeting of the British Medical Association, Dr. Reynolds, referring to a paper which he had read at the meeting of the Association in 1869, "On the Treatment of Acute Rheumatism by the Tincture of the Perchloride of Iron," gave the following record of his results: Of first attacks, forty-four per cent. were convalescent within the first week, while of those in their second, third, or fourth attacks, forty-two per cent. recovered within the same period.

Mr. Johnston (of Birmingham), in a paper on the same subject, supported the theory that the non-conversion of starchy food into glucose, and its conversion into lactic acid, which latter was absorbed into the system, produced the symptoms of rheumatic fever. He advocated the use of bicarbonate of soda, given in enema. He preferred soda to potash. In twenty cases treated in this manner, the temperature had fallen below the normal in the course of a week.

Dr. Fox (of Bristol), did not think that heart disease was a complication as often as had been generally represented, and thought that but few physicians were satisfied that the treatment advocated by Dr. Reynolds was superior to any other. He preferred the practice of frequent blistering of the joints, combined with the use of alkalis. Dr. Crighton (of Tavistock), had been treating cases with large doses of the tincture of perchloride of iron, combined with liquor ammoniac acetatis, with the result that the fever, which he thought would not otherwise have been subdued within six weeks, had subsided within ten days or a fort-

night. The accompanying heart diseases had also been very greatly reduced.

Dr. Stephenson (of Edinburgh) thought that in all such subjects the age of the patient should be remembered, and he believed that it was generally understood that after thirty a man's heart was pretty safe from the effects of acute rheumatism.

Dr. Meacham (of Manchester), who had experienced the disease in his own person, objected to blistering, but believed that the bicarbonate of soda was one of the best remedies for rheumatic fever or rheumatism, and should not object to taking two drachms when he suspected an attack was approaching.—*The British Medical Journal*, August 21, 1875.

TAR AS AN ANTISEPTIC DRESSING FOR WOUNDS.—In a communication to the Académie des Sciences of Paris, M. Sazarin states that after numerous experiments with different antiseptic dressings, he comes to the conclusion that vegetable tar (Norway tar was used) is an excellent agent for fresh, or already granulating wounds. Under its influence the granulations are small, red, and firm, and the pus thick and of good quality. When tar is applied to the wound by his method the parts smart at first, but this feeling soon passes off. The dressings can be left on some time without causing any irritation of the skin. The dressing is applied as follows: The wound is covered with a layer of tar extending to the nearest joint, if on an extremity; or some eight or ten inches over the borders, if on the trunk. Cotton-wadding, compressed with tolerable tightness, and the thickness of two fingers' breadth then covers the whole, and is kept there by a bandage. This dressing is again tarred over, and cotton and a bandage are again applied.

If the dressing be removed after ten, fifteen, or twenty days, a dry coating of wadding will be found adherent to the skin. At a short distance from the border of the dressing this coating brings away, when removed, the superficial layer of the epidermis, which forms with the tar and the wadding a soft, black membrane, adherent and strong, impermeable, and perfectly moulded on the surface of the extremity. This membrane is separated from the skin to a variable extent, according to the quantity of pus collected beneath it. Most excellent results were obtained in one case of amputation of the thigh, in two amputations of the legs, in two resections—one of the elbow and one of the knee—in five cases of suppurative arthritis of the elbow, and in several other minor cases.

LOOSE CARTILAGES IN THE KNEE-JOINT.—Mr. Jos. B.-H. recently removed a loose cartilage, the size of a filbert, from the knee of a man who had suffered from the characteristic symptoms for the past nineteen years. The operation was performed with antiseptic precautions; a drainage tube was left in the wound, the lips of which were closed by catgut sutures.

The tube was removed on the fourth, and the sutures on the tenth day, and by the twelfth day after the operation the wound was quite healed and the patient was able to walk.

Another case, reported by Dr. Williams, of the North Riding Infirmary, Middlesbrough, was of a man who first noticed trouble in his knee about four years before he presented himself at the institution. A portion of cartilage, the size of a sixpence, was removed by the antiseptic method, and the wound, the lips of which were not brought together by sutures, was dressed with Lister's antiseptic gauze, eight plies, and the limb placed in the extended position. In twenty days the wound had healed, each dressing having been done under the carbolic acid spray.

The cicatrix was strong, and he was allowed to walk about, which he could do perfectly. There was no stiffness or uneasiness in the joint, and he soon returned to his labor.—*The Lancet*, August 28, 1875.

A CASE OF IRREGULAR DEVELOPMENT OF PUSTULES AFTER VACCINATION.—Dr. Wiehen, of Hildesheim, reports that on May 6th, 1874, he vaccinated a healthy child, about a year old, with glycerine lymph, which had been kept for some weeks in a tube. With the object of procuring a good supply of lymph for future use, he vaccinated at eight points on each arm. Examining on May 13th, the eighth day, he was surprised to find but two pustules developed on one arm, and one on the other, while the other points of vaccination showed not the slightest sign of vesication. Three children vaccinated from these pustules took perfectly well and regularly. On May 18th, he happened to be again in the house of the first child, and the nurse called his attention to her arm, when he found the first were drying up, but that there were five vesicles in the first stage of development, and looking as if they dated from but three or four days before. They developed regularly and alike, having on the 22d the appearance of eighth-day vesicles. Dr. Wiehen feels at liberty to infer that the child had not attained immunity from the development of the first three vesicles, and was not protected until the 20th of May, otherwise the second five would have been abortive. He is inclined to the opinion that cases similar to the above may not unfrequently occur, but escape notice, because the physician does not visit the patient after the eighth day.—*Virchow's Archiv*, July 27, 1875.

ON THE TREATMENT OF ENLARGED GLANDS.—Dr. Morell Mackenzie states that after experimenting with various solutions, he has found that dilute acetic acid is the most valuable remedy. He injects, as a rule, once a week; but, where several glands are affected, the injections can be made more frequently. It is desirable, if possible, to cure by absorption; but sometimes suppuration cannot be avoided. In these cases the pus is to be withdrawn by a fine aspirator. Suppuration is apt to be followed by thickening of the walls or outer portions of the glands, and in these cases the oleate of mercury (ten per cent.) is most valuable. He does not believe that the cure of these cases renders the patient more liable to phthisis; he has seen many cases of phthisis develop where glandular enlargements had existed untreated; but he knows of none where pulmonary disease has followed the cure of such cases. On the other hand, he thinks that phthisis is more likely to follow the spontaneous breaking down of glandular tissue.

Mr. S. Messenger Bradley divides the morbid lymphatic tumors of the neck into three classes. 1. True hypertrophies, with or without a strumous diathesis, and showing no tendency to break down or undergo pathological change. 2. Strumous hypertrophies, consisting of cellular hyperplasia, plus caseous deposit, which after a time soften either in patches or entirely, until the gland becomes a mass of soft strumous matter. 3. Hard non-infectious lymphomata. For several months past he has injected the harder lymphatic tumors with a few drops of tincture of iodine, with the almost invariable result of causing a rapid diminution of the gland, going on to complete absorption. As a rule, two or three injections of from five to fifteen minims of the simple (P. B.) tincture of iodine are sufficient to effect a cure. No other treatment is necessary. He does not claim that this treatment is correct for all lymphatic tumors, and if used indiscriminately it undoubtedly will fall into dis-

favor. He makes the following divisions: 1. Cases to be treated by injection of iodine: (a) True hypertrophies of cervical glands without scrofula; (b) strumous hypertrophies of cervical glands before they have broken down; (c) hard (non-infectious) lymphomata; (d) all encapsulated tumors, as a tentative operation. 2. Cases to be treated by incision: Lymphatic tumors that have either broken down into pus, with or without previous injection of iodine. 3. Cases of cervical tumors to be treated by extirpation with the knife: (a) strumous glands which form tumors riddled with soft patches, and rest on a base of suppurating cellular tissue, with a large area of blue skin; (b) encapsulated tumors which have resisted treatment by injection.—*Trans. Brit. Med. Ass.—Brit. Med. Journal*, Aug. 28, 1875.

ON THE LYMPH AND LYMPHATICS OF THE LIVER.—Dr. Fleischl, observing that lymph obtained from the portal system of the dog after ligation of the ductus choledochus had a yellow tinge, concluded that this must be due to bile. After numerous experiments on cararized dogs he arrived at these results, viz., that when the natural channels for the bile are closed it makes its way into the lymphatics of the liver, and thence into the blood by the way of the thoracic duct; also, that if, besides the biliary, the thoracic duct be ligated, no bile, or only the merest trace, enters the blood. He thereupon sought, by means of injections, to learn in what way it passes from the bile ducts to the lymphatics. Making use of an injection of asphalt dissolved in chloroform, he found in the livers of rabbits that the solution passed from the bile capillaries into the lymph-vessels, those about the portal vein and under the capsule being filled. In the course of these experiments he also observed in the connective tissue surrounding the hepatic vein, lymph-vessels which emptied into the branches on the diaphragm, and judged that the lymph might escape from the liver in this way also. On dissecting out the twigs of the hepatic vein, and examining the enveloping connective tissue under the microscope, he found that it consisted of a network of coarser and finer filaments, resembling connective tissue, in the meshes of which were situated the hepatic cells. By another mode of examination he found that the coarser connective-tissue networks closely resembled in structure the external investment of the hepatic veins, but differed from them in being extremely delicate. They extended into the substance of the liver acinus, and did not merely invest the acinus, as hitherto supposed. The finer filaments have been described as the tunica adventitia of the capillaries. After injecting the bile ducts with osmic acid, Fleischl succeeded in demonstrating a further network of threads, having the character of the network of the biliary capillaries, and which should be regarded as such. He thinks his anatomical investigations raise serious objections to the present view of the formation of the bile in the liver-cells, and its subsequent passage into the bile capillaries.—*Bericht der k. Sachs. Gesellsch. der Wissenschaften.—Rundschau*, Aug., 1875.

A NEW SOLVENT FOR SALICYLIC ACID.—M. Rozsnyay states, in a communication to the *Pharm. Centralhalle*, that he has found in the sulphite of soda an agent which increases the solubility of salicylic acid, as well as its antiseptic properties. One part of salicylic acid, with the addition of two parts of sulphite of soda, dissolves in fifty parts of cold water, and forms a clear solution, which is not in the least degree irritating to an open wound. As a disinfectant he uses one part of the acid with from one to two parts of the sulphite of soda in from fifty to a hundred parts of water.—*Med. Chir. Centralbl.*, 1874, 26.—*Rundschau*, Aug., 1875.

THE MEDICAL RECORD:

New York, October 16, 1875.

MEDICAL PROGRESS IN AMERICA.

WE were not a little surprised to learn recently that a prominent London author asserted that medical books had a better sale in America than in London, and that this was particularly the case with English works. This is an admission which has a peculiar significance, as bearing upon a reputation which we have heretofore borne with our cousins for a want of concern in medical progress. There is no doubting the fact that the American medical profession is fast developing a habit for study, and an appreciation of its necessity, which augers well for the future. We have arrived at a point when we must cease to think of developing the country and turn our attention to developing ourselves. The medical requirements of our country are no longer so urgent as to require the services of indifferently educated physicians rather than be without them altogether. The number of the well-educated is now sufficiently large, scattered as they are over the length and breadth of the land, to meet the demand for thoroughly competent practitioners—in fact, with our present system of graduation, we are fast arriving at the point, if we have not already attained it, of overstocking the market. Naturally enough, the necessities of the case stimulate an active competition to excel, a generous rivalry to deserve a patronage which shall insure the requirements of a decent livelihood. Not only in the metropolitan centres, but in the most remote hamlet, this competition is active, for nowhere are any spare places vacant which enable any one practitioner to claim the unquestioned monopoly of the practice of any community. The same law which holds good in ordinary trade has an equal application to strictly professional pursuits—the greater the competition the greater the progress. There is no question that the one and only way to succeed is by a determination to keep up to the times, to be thorough and untiring students in our art, to strive in any and every possible way in our power to avail ourselves of all the means of

progress which the literature of our profession affords us.

As evidences of the right sort of understanding of the means to the end we notice the increased sale of standard works and the progress of medical journalism. As a notable example of the former fact we may refer to the flattering reception and substantial support of the publication of an Encyclopædia of Medicine, which is equal in extent and the number of volumes to a similar dictionary on general subjects. An enterprise, the failure of which a few years ago would have been a foregone conclusion anywhere, now commands a patronage in America which astonishes our European brethren. The undertaking has an importance which is far beyond any individual interests of the publishers, as affording not only an indication of the wants of the medical profession of this country, but of its determination to supply these wants. A short time since a leading newspaper alluded to the success of this stupendous work as one of the arguments to prove that the medical profession here led the van of all the educated classes in an enthusiasm for the study of their science.

But this, although a remarkable example of its sort, is by no means the only one which proves that we are waking up our energies for professional development.

The progress of medical journalism has of late been quite decided. It is true that numbers of journals have come into existence only to die, but this can hardly be laid to the blame of any lack of appreciation of the merits of journalism *per se*. The general explanation of this fact is, that those periodicals which failed were unworthy of success. There were never too many journals, but too few good ones. We believe the mistake has been in having too many periodicals which have been the organs of local influence. This has had a tendency not only to reflect discreditably upon legitimate journalism, but to rob it of much of the support and influence which was its due. It does not follow that because a village newspaper fails, a metropolitan daily should not succeed. We have no desire to uphold the larger journals which are published in medical centres at the expense of saying a good word for the many excellent ones that come from our smaller cities; but as we believe in the survival of the fittest, we are ready to prove that the metropolitan journals have the best chance. There is no lack of contributors to medical literature throughout the country; in fact, for reasons already stated, they are increasing every year; neither is there such a lack of appreciative readers to explain why medical journalism does not succeed better. But a great deal of the support to current medical literature runs to waste. Very many of the small and local journals are accountable for this. A college or a society organization feels that the interests of general medicine demand that it shall have an organ, and this being concluded, as a matter of course this organ must be supported pecuniarily and by literary contributions. As few outside the in-

fluences of the particular clique who publish the journal feel any interest in the success of the undertaking, the whole support necessarily falls on a comparatively few. As a natural consequence the journal fails; all the labor goes for nothing; all the papers specially written for the periodical drift into the oblivion of the rag-shop; the publishers are discouraged, the editor disgusted, and all who have been directly or indirectly interested in the undertaking are too willing to admit that the profession is behind the times, and has no appreciation of medical literature. These enterprises have, undoubtedly, a very bad effect upon real progress. How much better would the true interests of medicine be subserved by transferring all such supports to well-established metropolitan journals. Instead of having really valuable papers buried with the periodical in which they appear they could have a large audience and be preserved among the permanent records of our profession, doing good to all. Instead of taxing to the utmost the pecuniary capabilities of its few supporters, the same amount of outlay might give the contributor a subscription to every leading medical journal in the world. This narrowing of the influences of medical journalism is an evil which will eventually work its own remedy, the same as it has done in older countries. We are constantly hearing of the success of medical journals in Great Britain, but we forget to acknowledge that it is due in most part to a more or less concentration of local influences into central enterprises. We must recollect that these journals are published from the medical centres—in other words, the medical centres supply the whole kingdom. The encouragement of medical journalism in Europe is not much, if any, greater, in proportion to the medical population, than it is here, the only difference being that the varied interests are more apt to revolve around and acknowledge a common centre. But, as we have already remarked, we are pointing in this direction. The presumption that journalism is, on the whole, a failure in this country does not prove that we have not abundance of material to insure progress, but that we lack the means to direct our energies for progress in the proper channels for the greatest usefulness. Not only are we developing students, but the number of original workers is rapidly increasing in our midst, and American authorities are beginning to be respected on the other side of the water; not only are American works favorably received there, but American medical men are almost invariably treated with distinguished consideration.

America, it is true, is confessedly behind every other country in medical college education, but we have still hopes that she will in this, as in other matters, prove herself equal to the necessities of the times. Some of the drawbacks to medical journalism have a parallel in the medical college system. There are too many small colleges over the country that absorb the influence and support which legitimately belong to the

metropolitan schools. Already there are evidences of a strong professional sentiment in the proper channel, as is afforded by the steady increase of medical students in the latter institutions, and the proportionate falling off of attendance upon smaller schools. Taking everything into account, there is much need for encouragement; and while we strive to interpret aright our own position in relation to medical progress, we should not lose sight of the fact that there is still an abundance of room for improvement, an abundance of opportunity for the exercise of all our enthusiasm, and for the gratification of all our ambition.

MEDICAL REPRESENTATION IN THE SCHOOL BOARD.

IN another column we publish a letter on the sanitary care of our school children which should freshen the interest of the profession in this important subject. Dr. O'Sullivan, who has given so much attention to this matter, makes some statements in regard to the present school management, which offer much food for serious reflection. We agree with him in the recommendation to have the medical profession well represented upon the Board of Commissioners, and have so repeatedly advocated it that it has almost become a hobby with us. There will soon be some vacancies to fill, and this will be a favorable opportunity for his Honor the Mayor of showing how he can respect the wishes of the medical profession of the city.

THE NEW YORK HOSPITAL VACANCY.

IN the coming struggle for a position on the Staff of the New York Hospital, the claims of quite a number of applicants will probably be presented. The college influence will be strong. This is as it should be, for, as every one knows, the Hospitals were made for the Colleges. As we are in favor of a fair division of the spoils among the contestants, we would suggest that the appointing power consider the special claims of such as already have a number of hospital appointments. The principle which governs the chances of their positions is usually founded upon the fact that the more one has, the more he should have. There is one gentleman who holds eleven of these positions in the different medical charities, but as we understand that he is not an applicant, there is a reasonable chance for the next best man.

MEDICAL CONGRESS AT BRUSSELS.—The International Congress at Brussels was opened by the King of the Belgians, with great ceremony, on September 18th. His Majesty was warmly cheered by the assembly. Dr. Vleminckx was elected president, and Dr. Warlemont secretary-general, both being Belgians. Out of compliment, however, to the different foreign medical celebrities present, several honorary presidents were also elected, viz., Drs. Bouilland, Jaccoud, Larrey, and Verneuil (France); Mr. Bowman (England); Drs. Semmola, and Palascian (Italy); Drs. Langenbeck and Graefe (Germany), and Drs. Sigmund and Hebra (Austria).

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 22, 1875.

DR. F. DELAFIELD, PRESIDENT, IN THE CHAIR.

DIAPHRAGMATIC HERNIA.

DR. DRAKE presented a specimen of diaphragmatic hernia removed from a man aged 42 years. Two years ago, while at work on the 4th Avenue improvement, he was injured by a heavy stone falling on his back and driving his knees against his chest. He was examined by a physician, was told that he was hurt internally, and was sent to the 99th St. Hospital. There he remained for some time, during which period he vomited blood quite a number of times. He also had a great deal of pain in the left side, about the lower border of the ribs. He never enjoyed his usual strength, although he was able occasionally to work. On the 24th of August, while so engaged, he was seized with gripping pains; these were temporarily relieved by an anodyne. Being at the time constipated, and thinking that his pains might be due to such a condition, he prescribed cathartics for himself, without, however, any relief.

On the 27th of August the patient was admitted to the Hospital (Charity). On admission there was a slight tympanites, but the abdominal walls were not rigid, and there was no tenderness on pressure at any point.

This continued for three days, and being constipated he received one or two injections, and his pain was relieved by opium. His pulse was slightly accelerated, but there was no fever.

On August the 31st he was seized with nausea and vomiting. The tympanites increased very much, the abdomen became rigid, and there was tenderness in the left hypochondrium. His pain became more intense, and extended across the abdomen into the right iliac fossa. The second day the vomited material became of a dark brown color. He gradually sank, and died on September 2d.

The autopsy was made by Dr. Bacon. On opening the abdominal cavity the intestines were very much injected, and were matted together by a fibrinous exudation. The abdominal cavity was filled with fecal matter mixed with some dark fluid. The splenic flexure of the colon was found protruding into the pleural cavity through the diaphragm, carrying with it a portion of the omentum. The hernia was strangulated and black. Just as the intestine passed into the opening was a spot of ulceration. In the pleural cavity there was four ounces of blood. There were no adhesions in the pleural cavity, nor any other evidences of pleuritis.

TAPPING IN OVARIOTOMY.

DR. SELL presented two vials containing the contents, respectively, of two ovarian cysts which he had tapped. The first fluid was of a brownish-red color, and was removed from a woman with the following history:

She came to this city, on the 12th of June, from Greenport, Long Island. She was then very large, and was suffering a great deal from pain. Having travelled all night by boat, and being compelled to sit up throughout the whole journey, she was considerably exhausted on her arrival, and only called on Dr. Sell that afternoon for an opinion. She had been tapped

twice during a period of three months. The last operation was performed in a very unskilful manner by a lancet, giving exit only to a half of the contents of the cyst. This operation was, according to her account of the symptoms from which she afterwards suffered, quite a disastrous one. She evidently suffered from peritonitis, the result of the escape of some of the contents of the sack into the abdominal cavity.

The patient was tapped by Dr. Sell that same afternoon, and forty pounds of fluid (sp. gr. 1.020), containing pus, blood, epithelial scales, and the regular ovarian granules. She was at once relieved of her symptoms, and was able to return to Greenport the following Monday. Being in rather emaciated condition, she was sent home to recruit and prepare herself for the operation of ovariectomy. He had since heard from her that she had filled larger than ever, but was in splendid condition otherwise; all of which seemed to Dr. S. to prove the advantages of judicious tapping.

The second fluid, which was of milky leaden color, was taken from a German woman, aged 33, who after having run the gauntlet of ten unsuccessful diagnoses from as many different medical advisers, finally came to consult Dr. Sell. She commenced to menstruate when she was fourteen and a half years old, and continued regular up to two years ago. The intervals of her catamenia varied from once in four to once in eight weeks. She was married when she was twenty-four, but had never been pregnant.

During the month of April she noticed that her abdomen began to enlarge, and then began the series of consultations which so materially helped to make her lose confidence in the diagnostic art. She was variously treated for fever, suppression of the menses, change of life, disease of the liver, lungs, kidney, in fact for every disease save the right one, until Dr. Sell saw her. On that occasion she visited the Eastern Dispensary in a very enfeebled condition, from a diarrhoea, from which she had been suffering for some time. She was then informed that in addition to catarrhal diarrhoea she had dyspepsia, hepatic engorgement, and ovarian disease, and that in all probability the contents of the cyst were discharging per rectum. Dr. Sell drew off about a quart of the fluid presented, when the patient was relieved and improved in all her symptoms.

CONGENITAL SARCOMA OF RADIUS.

DR. POST presented a specimen of congenital sarcoma, which was situated in the lower part of the forearm, corresponding nearly to the lower half of the radius. Dr. Post saw the child, with Dr. Warner, when it was about a fortnight old. The tumor had been noticed at the time of birth, when it had a certain degree of hardness. The integument was of a reddish color, and presented a vascular appearance, suggesting the idea of malignancy. It was at first agreed that an attempt should be made to discuss the growth by means of electrolysis, but it gave rise to such a formidable hemorrhage from the places where the needles were inserted that amputation became imperative. The operation was performed on the thirty-second day, the section being made at the elbow-joint.

The specimen was examined by Prof. Arnold, who described it as a soft sarcoma with oval and fusiform cells and slight traces of atheroma. The mass seemed to be connected with the periosteum covering the radius. There was no history of malignant disease in the family. In conclusion, he remarked that the specimen in question was of great rarity.

DR. DELAFIELD referred to similar ones reported by Mr. Bryant in the last volume of Guy's Hospital Reports.

SPINAL CORD COMPRESSED IN CARIOUS VERTEBRÆ.

DR. V. P. GIRNEY presented a specimen of spinal cord with the following history:

On the 18th day of August, 1874, Albert Stuckey, a poorly nourished boy, 6 years of age, was admitted to the Hospital for the Ruptured and Crippled. Ailment: caries of the dorsal spine, eighteen months' standing, with consequent paraplegia of four months' standing. The father, a moderately healthy man, reported that the child had always been delicate, and that the mother died an epileptic. No reliable history of a fall obtained.

Examination revealed a marked prominence of the middle dorsal vertebra and the anterior thorax, no sign of congestive abscess, and a complete loss of voluntary power in inferior extremities, with reflex excitability preserved, a tonic spasm of flexors and adductors, and tremor on passive motion. The sphincters were very deficient in contractile power.

A spinal brace was applied, and each day the boy was placed on his feet. In October an ophthalmoscopic examination revealed a congested disk, nothing more.

By the following February the excreta, in spite of the utmost vigilance a hospital can command, had caused considerable excoriation over nates and thighs. These were soon relieved, but an occasional diarrhœa, with a toneless sphincter, would thwart all efforts at repair. Ultimately bed-sores formed over the trochanters. Finally, on August 9th, personal attention was begun. With carbolized water he was sponged and shampooed twice a day. Stimulants and tonics were used unsparingly. Within a week great improvement. A chill, however, on the 23d, with hurried respiration, called my attention to the thorax, and, anteriorly, to the right, were heard crepitant râles, well marked on the second day. Large doses of quinine once a day as an antipyretic were only partially successful. The pneumonia was completed by the fourteenth day, but a fatal adynamia followed, so extensive had been the sloughing about the nates, and death supervened on September 13th.

At the autopsy, ten hours after death, Dr. E. G. Janeway officiated, and the following notes were taken: Body extremely emaciated, bed-sores over each hip, marked spinal curvature from the first to the twelfth dorsal vertebra, forming rounded arch with the summit at sixth, seventh, and eighth. Lungs slightly œdematous, with a few subpleural ecchymoses and adhesions, most marked on left side. Heart and kidneys normal. Liver appears normal, with the exception of a slight, possible waxy change.

On opening body, lying in the spinal concavity was found a sac, two inches vertically and three and a half laterally. The contents—a cheesy, curdy mass. Walls formed by anterior common ligament, thickened connective tissue, and pleura. On making vertical section of spinal column, from before backward, body of eighth dorsal vertebra entirely gone, seventh nearly so, and sixth and ninth partially. Pultaceous matter lay in place of the eighth, pressing on the spinal cord, which at this point was found anæmic, yellowish, and smaller in size. The absence of blood-vessels here was notable. (The cord is now in process of hardening for microscopic section.) A portion of the gastrocnemius under the microscope showed granular and fatty globules, muscular striae lost, and occasionally a homogeneous mass.

DR. JANEWAY remarked that the interesting point in the case was the absence of blood-vessels in the portion of the cord presented. This portion corresponded to the point of pressure, and was doubtless caused by it. It belonged to a series of cases in which recovery

was easily explained by the subsequent restoration of motion, the result of the establishment of circulation in that part by the removal of pressure.

DR. DELAFIELD asked if inflammation of the cord would not produce subsequent atrophy.

DR. JANEWAY did not doubt the fact, but he had never seen such a case recover.

DR. POST referred to a case which had come under his observation, and in which, from disease of the vertebra prominens, there was a paraplegia which had been permanent, existing during the whole of a period of four years, while the patient was under his observation.

DR. PO K, in this connection, referred to a case of paraplegia which had died in Bellevue Hospital. The autopsy had been performed by Dr. Delafield, and there was neither disease of the spine nor of the cord to explain the symptoms.

The Society then went into executive session.

Correspondence.

PENETRATING GUNSHOT WOUND OF ABDOMEN—PASSAGE OF THE BULLET PER RECTUM—RECOVERY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I beg leave to add the following case to the similar ones already reported by different correspondents:

A healthy soldier—one of the so-called "Louisiana Tigers"—was wounded at the battle of Gettysburg, July 3d, 1863, by a rifle bullet penetrating the abdomen, just at the point of the ensiform cartilage. He reported that he was considerably stunned and continued insensible for some time, and was obliged to lie where he fell until the 5th—two days—when he was removed on a stretcher to the Presbyterian Church Hospital. The wound presented the ordinary appearance, seeming to involve the stomach at the lesser curvature; abdomen somewhat tympanitic, very tender on pressure down to umbilicus; knees drawn up; but little pain complained of, except on motion. He was made as comfortable as possible; the wound cleansed and treated with water dressing, and morphia administered, together with suitable nourishment.

On the 7th he was suddenly seized with very severe colic, accompanied by vomiting so obstinate that, other remedies failing, chloroform had to be used for several hours, when entire relief was obtained. No other unpleasant symptoms occurred, and the case progressed favorably, the patient feeling well, with a hearty appetite and a good digestion, the bowels moving naturally every other day or so, the passages, at first dark and tar-like, becoming healthy in time.

On the 13th—ten days after being wounded—he passed the bullet, imbedded in a mass of natural feces. It was a little flattened on one side, towards the point, as though it had glanced off some solid obstacle—perhaps his belt-plate. After this he improved rapidly, the symptoms of peritoneal inflammation disappeared; he refused to remain in bed any longer; took the regular convalescent fare, reporting daily at sick-call for about two weeks, when, appearing perfectly well, he was sent away with other prisoners.

Surgeon W. H. Rulison, of the 9th New York Cavalry (afterwards killed in action), and Assistant Surgeon George McGill, U. S. A., took especial interest in the case, and the bullet was given to Surgeon Brinton,

U. S. V., for preservation in the Army Medical Museum.

Penetrating Gun-Shot Wound of Abdomen—Death in Seventeen Days from Pyæmia.

At a subsequent period I made a post-mortem examination of a soldier who had been wounded by a compound rifle bullet, in the left hypochondrium, just below the margin of the twelfth rib, and lived seventeen days. I traced the bullet into and out of the stomach, one portion passing down the left side, along the spine, and lodging in the psoas muscle; the other, accompanied by a shred of his blouse, burying itself in the right kidney. In this case, after seventeen days, and a journey of nearly a thousand miles in railroad cars, steamboats, and ambulances, the stomach was found partially filled with food in process of digestion, quite healthy, and not at all inflamed or softened, only slightly congested, and indurated to some extent around the wounds, which were entirely healed and closed perfectly, death being caused by pyæmia from psoas abscess and ulceration of the kidney, thus fairly proving that the stomach is not liable to take on morbid action of a fatal character from penetrating wounds, unless tortured into inflammation by the probe, or otherwise unskillfully treated.

In connection with the case lately reported by Dr. O'Meagher, of New York, I venture to think the foregoing cases may not be uninteresting.

H. D. VOSBURGH, M.D.

LYONS, N. Y., August 19, 1875.

GUNSHOT WOUND OF ABDOMEN.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—The three cases of gunshot wounds of abdomen, recently reported in the RECORD, recall to mind a very singular case, which occurred in my regiment during the late war.

Private R. S. Langworthy was wounded at the battle of Drury's Bluff, on May 16, 1864. The ball entered at the umbilicus, making a somewhat lacerated and large wound, considering the size of the missile. A portion of the ileum protruded, so that when I first saw him in the evening, after the battle, the hernia was as large as my fist. With the valuable assistance of Dr. Squires, of the 89th N. Y. Vols., and the late Dr. Snow, of the 100th Engineers, we succeeded, after carefully washing the intestine with warm water and condensed milk, in replacing it. He had been without nourishment all day, and when we finished dressing the wound he was so much prostrated that we had but little hopes of his recovery; however, we gave him the best care our little field-hospital could afford, and in the morning he had rallied nicely, and was in good spirits. We found it necessary to catheterize him for four or five days, when he so far recovered that he could void his urine with but little difficulty. And I sent him to Hampton Hospital, at Fortress Monroe, about twelve miles in ambulance and forty-five miles by transport. He had been at the hospital five weeks when he voided the ball. A few weeks after he was sent home to Brookfield, in this county, where he now resides, and has fair, but not good, health, as he has not recovered from the effects of the wound. The wound healed in nearly six months, leaving a large umbilical hernia.

H. W. CARPENTER, M.D.,

ONEIDA, NEW YORK.

Late Surgeon, 117th N. Y. Vols.

MEDICAL REPRESENTATION IN THE SCHOOL BOARD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The article on "Sanitary Reform in our Schools," suggests a few reflections which with your permission I will briefly state. Before doing so, however, permit me to say that I have read the article referred to with interest. The suggestions are made with the precision and comprehensiveness which have characterized your editorials since the question of "Sanitary Reform in our Schools" has been mooted. In a review of my first Annual Report to the Department of Public Instruction of this city, April, 1872, the necessity of medical inspection was clearly demonstrated, and remarks were made commendatory of the institution of medical inspection by the late Board of Education. The article gave the public and the profession a view of the unsanitary condition of our public schools, of which they had not up to that time any adequate knowledge. The suggestions made in reference to the action of the section on public health of the British Medical are good as far as they can be practically applied to our system of public instruction. Past experience gives us no ground to expect that suggestions made by health officers to school boards would be properly tested, or that any practical effect would ensue. A proposal requiring a certificate from a medical officer of health as to the construction of school buildings, and their adaptation for educational purposes, might be carried out in Great Britain, but it is doubtful if such a wholesome sanitary provision would be successfully enforced here, as political interference would no doubt naturally modify the results. There has been scarcely any change in the construction of our school buildings for the past twenty years. The same defects as to construction of class-rooms, heating, seating, still remain. I could go on enumerating, did space permit, other grave sanitary defects in the construction of those buildings of which our school managers seem to be entirely ignorant, and they obstinately ignore all suggestions tending to correct them. The more we investigate this matter, the more glaring the defects appear. That a reform in our school management is necessary no sane person can doubt. This desirable result is not likely to occur until there is a change in the personnel of the present school board—a result, it is hoped, that will soon ensue, as there has been lately several resignations, and the term of a third of the members expires this year. Should we not have a representative of the profession as a member of the Central Board of Education? The physical wants of 100,000 children demand it; lawyers, bankers, and politicians are there, but no physician. Is it not time, Mr. Editor, that this subject should be considered, and the claim of the profession recognized?

Respectfully yours,

R. J. O'SULLIVAN.

INSTRUCTION IN COOKING.—The School Board of London has arranged to have three hundred girls, selected from its schools, taught the art of cooking by the teachers of the National Training School. Five free scholarships have been offered by the Society of Arts, and the Educational Department gives about one dollar a year to public schools on behalf of each girl who is taught cookery according to the recognized code.

"SUCCESSFUL PRACTITIONERS."

TO THE EDITOR OF THE MEDICAL RECORD.

MR. EDITOR:—I have been much amused, and I hope edified, by the perusal of the letters of your correspondents "Diploma" and "Success," but I was totally unprepared for such a shock as I received upon reading the communication of M. D. V. S. Even now, I can scarcely believe that it is not a huge joke, perpetrated by some quizzical *successful* practitioner. There was a time, sir, when it was deemed an honor to belong to a learned profession—when a degree in divinity, law or physic conferred dignity upon a man; but O tempora! O mores! how have the professions fallen from their high estate. Quackery abounds in all of them, but the temples of Æsculapius have been most befouled by his priests.

Under the pretext of ministering to the public weal, we have advertising in its most specious forms. We find dispensaries, private and municipal, parading their special advantages, thereby cheapening physic, and indirectly calling attention to the superior qualifications of their medical staffs. We have medical bath-houses, mineral springs of all kinds, with "medical directors" or superintendents in charge; "homes for invalids," "private hospitals," and "retreats" of all sorts kept by medical boarding-house keepers, who board, lodge and physic their patients for a consideration. Then we have medico-chirurgical *tradesmen* or *mechanics*, under which heading may be classed the makers of artificial legs, braces, abdominal supporters, etc., who flaunt their easily acquired M.D. in every public print, and trade under the grandiloquent titles of orthopaedic or mechanical surgeons, electricians, etc., etc. Passing by (with due reverence) the female doctors (why not doctresses?), we come to the dentists—always a most useful but humble class—whose use of that absurd degree "D.D.S." has played sad havoc with that ancient and reverend title Divinitatis Doctor. And here let me ask why the coppers, leechers, barbers and nurses are left without a degree? We have already Tennessee "Doctors of Pharmacy" to confound with the Ph. D.'s; and to cap the climax, we are to have doctors of veterinary medicine, "a sister branch" of our divine art, as your correspondent M. D. V. S. most facetiously calls it.

Heaven help the profession of physic, when its disappointed members shall be obliged to become "horse doctors," even though "the financial rewards be satisfactory to the most sanguine." Seriously, Mr. Editor, did your correspondent M. D. V. S. intend to insult the profession? E. N. R. O. B. E. L. C.

PORTSMOUTH, N. H., 28th September, 1875.

THE ELECTROLYTIC TREATMENT OF TUMORS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the issue of the RECORD for Oct. 2, Dr. Comegys raises the interesting and practical query, whether electrolytic treatment may not, in some cases, change a benign into a malignant tumor, or hasten the growth of a tumor already malignant.

In answer to this query I may present these conclusions, drawn from my own experience:

1. Large, solid malignant growths, that are rapidly growing, may have their growth hastened by the irritation of electric treatment. I have seen this effect produced in one case of scirrhus of the female breast, and only in that case, although I have treated a large number of malignant tumors in this way. I have used

only the galvanic current, with the needles; never the faradic, except externally.

The claims which have been made, that electrolysis causes rapid and permanent absorption of hard, solid, malignant growths, and ultimate cure of the constitutional taint, have not been confirmed by my experience, nor by the experience of any with whom I am acquainted.

2. It is entirely conceivable that a tumor such as Dr. Comegys describes, already sufficiently malignant, to recur after removal, might become more so, and might have its growth hastened by three months' treatment with needles, connected with the *faradic* current. Treatment, such as that, is not called for in any case of tumor, malignant or benign. Those of us who accept the theory, that malignant tumors are excited, in some cases at least, by local mechanical injuries acting on a predisposed diathesis, will find it not difficult to believe that the faradic current (the effect of which is mainly mechanical) might, when introduced recklessly and for an excessively long time through needles, heighten the malignancy of a tumor.

3. Cystic malignant tumors may be greatly reduced in size, and their progress apparently arrested by electrolysis.

One striking case of this kind—a large malignant cystic of the female breast—was reported by me about two years ago. The patient, at latest accounts, was well, although a small lump remained in the breast. Before treatment by electrolysis immediate removal had been advised and urged by competent and careful surgeons.

4. All painful tumors, whether solid or cystic, may have their pain relieved by electrolysis, or by single external electrization, even when they are rapidly extending and have arrived at the hopeless stage. This result is a matter of frequent demonstration.

5. If electrolyses be used at all for solid, rapidly extending malignant tumors with the idea of eradicating them, the needles should be inserted in the base of the tumor, or the base may be worked up electrolytically after the tumor has first been removed in the ordinary way. This method of treatment that I have used for four years is in the same line as that by arsenic paste, and like that, it seems to have theoretical and practical advantages over the ordinary methods, provided the disease be not too far advanced.

There would appear to be less liability to shock after electrolysis than after cutting operations, since the stimulus of the current opposes a tendency to shock. Furthermore, there would seem to be less danger of pyemia after operation by electrolysis or galvanocautery than after similarly extensive operations with the knife or ligature. I form this opinion, which it is impossible to prove statistically, from watching the results of very many operations in various parts of the body, and from the general experience of surgeons with whom I have conversed on the matter.

6. In naevi, external and subcutaneous, in goitres of moderate size and consistency, in benign cystics and in some fibroids, electrolysis has oftentimes great advantages. Much depends, however, on the nature and locality of the tumor and the details of the treatment. GEO. M. BEARD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the MEDICAL RECORD of Oct. 2, there is a report of a case of recurrent tumor of the neck, and it is stated that in the treatment, the interrupted current, that is the faradic or induced current, was employed, and the conclusion arrived at was, "that this electric treatment converted this recurrent fibroid into a malign-

nant tumor, or at least very much hastened its degeneration into one." Now for the removal of tumors, certainly a strong chemical or electrolytic effect is required; why then should the faradic current be employed, which as developed in the ordinary induction instrument has scarcely any electrolytic action? That is employing an agent to perform a certain work which it is not capable of doing, for the faradic current is strongly stimulating, but not capable of developing electrolytic action.

The difference between the two currents is not, as stated, one only of *tension*. To quote from Onimus in the "Practitioner" for Sept., 1874, when speaking of the difference of action between the induced and continuous currents, "Induced currents having a great tension, will cross tissues very easily, and determine a molecular shock, but will exert no chemical action;" and of the constant current, "It is during this silent period, when nothing seems to act, when the organs are in apparent rest, that the principal action of the continuous current makes itself felt in the depths of the tissues; it is during this period that are produced electrolytic effects, phenomena of transference and influences of orientation, all which things never exist with induced currents." The difficulty not only in this case but in others, appears to consist in confounding the therapeutical effects of the faradic and galvanic currents; in fact, not only are the two currents different in their action, but as experimentally proved by Radcliffe in his "Dynamics of Nerve and Muscle," the positive and negative continuous currents produce disproportionate effects: the muscular contractions of a prepared frog, on closing and opening the circuit, coming to an end in 60' in the one case and in 15' in the other case.

The want of success in this case should not then be attributed to the electrical treatment, since the current employed has no deobstruent effect.

It is also stated that "the principal other methods of treatment are by caustics, ligature and the knife," thus ignoring that most excellent and highly successful treatment by the galvanic cautery.

DAVID BENSON, M.D.

HOBOKEN, N. J.

A LARGE MOUTH.—The *Medical and Surgical Journal* says that Dr. Robinson, of Rome, N. Y., took the impression of the jaw of a colored woman, which measured three inches from front to back, and three inches across, the usual dimensions being only one and a half by two inches. This is said to be the largest mouth known to the dental profession of this country.

M. LEHNERT, veterinary surgeon, reports a case of Cæsarean section in a cow suffering from plithisis pulmonalis, and on the point of death. The operation was so far successful that three healthy calves were brought into the world, and, he adds, were afterwards successfully raised.

SIR C. LOCOCK left a property valued at something less than one hundred thousand pounds; the most noticeable provisions of his will being that his remains should be buried in Kensal Green, in an unostentatious manner, and that, in the event of his death occurring from any obscure or doubtful disease, his remains should be subjected to post-mortem examination.

SCARCITY OF PHYSICIANS IN SIBERIA.—Siberia, according to a report addressed to the Russian Government by General Kasuakose, has only fifty physicians. To remedy this deficiency, the Government has resolved to establish an university at Tomsk.

New Instrument.

AN APPARATUS TO FACILITATE THE REDUCTION OF DISLOCATIONS.

MANY persons are familiar with the "Indian puzzle" made of basket-work in the form of a long cone, and may have been surprised at the tenacity with which it seized the finger, which they had inserted into the open extremity, when traction was made upon the other end. In 1847 Dr. Frank H. Hamilton called attention in the *Buffalo Medical Journal* to the use which might be made of this toy in reducing dislocations of fingers; and in the second edition of his work on Fractures and Dislocations, page 603, he gives a picture of the instrument. Dr. Oliver Wendell Holmes also recommended the Indian puzzle for the same purpose in the first Volume of the *Transactions of the Amer. Med. Assoc.*, but the probable reason why it has not been more generally adopted is, that these minor dislocations are, as a rule, reduced without the need for any other than the simplest means. Quite recently, however, some of our instrument makers have constructed an apparatus upon the same principle, but in sizes large enough to admit of its being applied to the arm, leg, or thigh, and we are indebted to Mr. Reynders for an opportunity to examine a set of these tractors and for the cut appended.

When a "good hold" is the desideratum, nothing could be more perfect; and to remove it, all that is required is to stop pulling and approximate the ends of the basket-work, and by gaining in breadth what it loses in length it becomes loose enough to permit the limb to move freely in or out.

ANTI-VACCINATION IN MONTREAL.—Of late years small-pox has been very prevalent in Montreal, especially among the French population, and in consequence the Provincial government recently passed an act to empower the municipal authorities to enforce vaccination. The attempt on the part of the authorities to do so has been resisted by the French Section of the community, under the leadership of a Dr. Codine and other physicians, and a mob of seven thousand persons assembled a few Sundays since, stoned the aldermen and gutted the house of one of the supporters of vaccination. The police seemed to be utterly powerless, and a severe epidemic of small-pox, which exists, is the natural accompaniment of the troubles.

DR. E. KRACKOWIZER.—At a stated meeting of the New York Medical Journal and Library Association, October 1, 1875, the President, Dr. Peaslee, announced the death of Dr. ERNST KRACKOWIZER, and upon motion appointed a Committee to draft appropriate resolutions relating thereto, Drs. Noeggerath, Guleke, Althof, F. H. Hamilton, A. C. Post, and Gordon Buck.

Obituary.

CYRUS WEEKS, M.D.

DR. CYRUS WEEKS, who was suddenly killed on the 20th of September by being run over by a train in the Morris & Essex R. R. depot, as he was about to go to his country home at Bloomfield, N. J., was the son of Captain Coles Weeks, a volunteer in the war of 1812, and was born at Sandbornton, N. H., on the 16th of November, 1806. Like his father, he was a man of tall and commanding figure, and in his general appearance was calculated to inspire confidence. His early education was received in the public schools and the academy of his native town, and in 1826 he commenced the study of medicine with Dr. Durgin, in Portland, Maine. In 1829 he graduated in medicine from the medical department of Harvard University, and in the following year commenced practice in this city, his office being successively at the corner of Grand and Elm streets; at Howard and Mercer streets, where he was associated with Drs. Dickson and Wooster; on Broome street, between Crosby street and Broadway; in Spring street, near South Fifth Avenue, and lately at 42 Clulton Place. Dr. Weeks was remarkable for his devotion to his professional duties, and during his professional career he acquired one of the largest practices in the part of the city in which he lived. He was equally noted, however, for his benevolence, and it is said that out of a practice worth at least \$10,000 per annum he rarely managed to collect more than \$4,000. His obstetrical practice was especially large, and it is also reported that he had attended more cases of labor than any other physician in the city.

During the several epidemics of cholera which have visited the city Dr. Weeks was an active worker, and twice contracted the disease. He was one of the two physicians appointed to investigate the causes and nature of the epidemic of typhus which visited the city in 1846 and '47, and the exhaustive report which they presented was mainly drawn up by him.

In addition to his labors as a physician Dr. Weeks found time to contribute to the secular press, and Godey's and the Knickerbocker Magazine contained several articles from his pen. His house was long known as the home and headquarters of many of the literary people of the city. Horace Greeley and Dr. J. W. Francis were among his common associates, and *The New Yorker* and *The Tribune* received many contributions from him while Mr. Greeley was alive.

The death of Doctor Weeks removes another of the class, already too few, who are spoken of as gentlemen of the old school, and leaves us a memory of one who, in his character as a Christian man and a physician, is worthy of close imitation by the generations who are taking his place.

SOUTHERN MEDICAL SOCIETIES.—The Association of Medical Officers of the Confederate Army and Navy, and the sixth session of the Medical Society of Virginia, are to be held in Richmond, the former on the 19th, and the latter on the 20th inst.

DUCHENNE DE BOULOGNE, whose illness we recently noticed, has since died, having suffered an apoplectic attack, from the immediate effects of which he partially recovered, but lived only a few weeks thereafter.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Oct. 3d, 1875, to Oct. 9th, 1875.

SMITH, J. R., Surgeon.—Leave of absence extended 20 days. S. O. 197, Mil. Div. of the Atlantic, Oct. 2, 1875.

WEBSTER, WARREN, Surgeon.—To report to the Commanding General Mil. Div. of the Atlantic for assignment to duty. S. O. 201, A. G. O., Oct. 6, 1875.

JANEWAY, J. H., Assistant Surgeon.—To report to the Commanding General Dep't of the South for assignment to duty. S. O. 201, c. s., A. G. O.

PAULDING, H. O., Assistant Surgeon.—Assigned to duty at Fort Ellis, Mon. Ter. S. O. 190, Dept of Dakota, Sept. 29, 1875.

NAVY.

October 10.

KIDDER, J. H., Passed Assistant Surgeon.—Detached from temporary duty on board the *Blue Light* and placed on waiting orders.

THE LATE DR. FOSTER SWIFT.—At a stated meeting of the New York Academy of Medicine, held October 7, 1875, a Committee, consisting of Drs. John C. Dalton and G. M. Smith, presented the following preamble and resolutions, which were unanimously adopted:

Whereas, The members of the Academy have learned with regret of the death of their former associate, Dr. Foster Swift; therefore,

Resolved, That in Dr. Swift the Academy and the profession have lost a member whose personal character commanded the esteem of all who knew him; whose brilliant talents gave sure promise of future distinction, and who was eminently fitted by his superior attainments, his singleness of purpose, and his engaging manners, for a prolonged life of usefulness and success.

Resolved, That a certified copy of these resolutions be transmitted to the family of Dr. Swift, as an assurance of the sympathy of the Academy in his loss, and of their high appreciation of his personal and professional qualities.

Resolved, That a copy of these resolutions be published in the medical journals of this city.

SAMUEL S. PURPLE, M.D.,

W. T. WHITE, M.D.,

President.

Secretary.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

[THE MEDICAL RECORD is published every Saturday. Notices of meetings, lectures, operations, etc., intended for publication in this bulletin should be received at the office, 27 Great Jones Street, one week previous, to insure their appearance.]

Monday, Oct. 18th.—Section of Obstet. and Dis. of Women and Children, N. Y. Academy of Med., 12 W. 31st st.

Tuesday, Oct. 19th.—Med. Soc. of the County of Kings.

Friday, Oct. 22d.—Medical Library and Journal Association, 107 E. 28th st.

Original Lecture.

ON THE TREATMENT OF TYPHOID FEVER.

By W. H. THOMSON, M.D.,

PROF. OF MATERIA MEDICA AND THERAPEUTICS IN THE MEDICAL DEP. OF THE UNIVERSITY OF THE CITY OF NEW YORK.

LECTURE II.

GENTLEMEN:—To illustrate the statements made towards the close of my last lecture, I here show you two charts—the first from Liebermeister, exhibiting a diagram of the typical thermometric range in a case of typhoid fever allowed to run its natural course. You see that during the first week the rise is steadily up to a figure which it maintains then with a general degree of evenness throughout the second and third weeks, but characterized by a morning remission and afternoon, or early evening, exacerbation. During the first week the evening point rises above that of the preceding day, so that the remission of the following morning occupies nearly the same level with the highest mark of the day before. During the fourth

with occasionally in typhoid, and always indicate severity of infection. The next day his temperature rose to nearly 106° , and I determined to have recourse to the ice-water bath. He was in it on the first occasion thirty-three minutes before the thermometer had fallen sufficiently, as I thought, to have him removed. Now on the chart the dark line marks the mean morning and afternoon degrees, but the dotted line is introduced to show the effect produced by the baths; the figures at the top of the dotted line indicate the temperature of the bath; the figures at the small straight line crossing this below, indicate the number of minutes he was in the bath; and the figures at the bottom show how many minutes after he was removed to bed the temperature continued to fall; each cross line on the chart also enabling you to see to what an extent the total depression was. You will note also that the dotted line always begins with a rise, which represents the temporary exacerbation of the fever by the bath, to which we have alluded. Now in looking at this chart you see at once that the general range of the fever during the second and third week was about as uniform as in the first chart, but with this great difference, that the range of the two days preceding our beginning with the baths, was advancing to a most perilous height, from which it was permanently deflected to a lower and safer level. This was done by

No. 1.

week the earliest indication of defervescence is seen in an increasing descent of the line indicating the morning remission, the high figures of the afternoon not declining till later.

The second diagram represents the course of the fever in a patient of my own treated by ice-water baths, and which has been made by my friend Dr. F. H. Rankin, who also ably superintended the administration of the baths and took the observations. He was a young gentleman whom I was called upon to treat in July of last year, and I first saw him on the eighth day of the disease, he having contracted the fever when away from home, and as he thought, with much reason, from the water he drank in a neighboring city. It was well water, but he said that its offensive odor was such that he could scarcely drink it. When I saw him he had already considerable tenderness on pressure over the cæcum and violent diarrhoea, but this was soon checked without the use of astringents, as I will explain, and it never recurred during his whole subsequent fever. Meantime his fauces, tonsils and the roof of his mouth were covered with a white diphtheritic membrane, and his voice was much altered. Such exudations are to be met

the administration of but two, and only twice, three baths per diem. Now it may seem to you that a daily change of but a degree and a half on the average does not amount to such an important difference, but that degree and a half extended over twenty-four hours would equal of itself the sum total of fever during a smart attack of ague, and I doubt whether the strongest among you, if he experienced an intermittent of that degree, would not feel as if he had lost a great deal of his accustomed power and vitality, though only for a day. When, however, you add such an exhaustion to the consuming pyrexia of typhoid it may easily be enough to prostrate fatally the sufferer.

The indications for reducing the degree of pyrexia have led modern physicians to seek for medicinal agents which would subserve this purpose, in addition to the abstraction of heat by the external application of cold. Chief among the drugs which have been demonstrated to lower the temperature of the body, both in health and in disease, stands quinine, when administered in sufficient doses. It has therefore become quite the fashion of late, among the German school of physicians especially, to give doses of from 30 grains

to obtain a desired reduction of pyrexia in typhoid fever with cold baths and quinine (which I have not done yet). I believe I would try the above-mentioned prescription first, in preference to the digitalis, giving it as often as every two hours, and watching carefully for the first sign of intermission of the pulse, for this, or a plain slackening in its rate, always precedes for a considerable time the nausea and prostration from these agents. It is to our German brethren that we owe the modern introduction and perfection of a system of antipyretic treatment which experience has vindicated as the greatest advance gained in therapeutics for many years. Statistics are uncertain only when used in an unscientific way, but few can doubt that the verdict of carefully sifted observations is now unanswerably given in favor of the new method, under which typhoid fever, from being the most dangerous of the acute infectious diseases of Germany, has on the same ground been robbed of more than half its former list of victims.

We come now to the management of the second great complication of typhoid fever, namely,

STARVATION.

The primary cause of this we have already shown to be from the suspension of the secretions of the digestive glands, by the effects of a too heated blood perverting or abolishing gland-function generally. You will therefore invariably find such suspension more or less complete, according to the greater or less amount of fever present. This fact is well illustrated, for example, in intermittent fever; for while a patient is in the hot stage of the attack, with a temperature of 104° F. or 105° F., his stomach is so irritable from its dry and congested state, that he not only cannot think of taking solid food, but will most likely at once reject it by vomiting, the same as he would reject some totally indigestible article, if it happened to be swallowed in health. On the other hand, during the intermissions, especially in cases of tertian and quartan ague, while the blood temperature is normal, the appetite is frequently strong and the digestion good. I remember that in my own case once, while suffering from a quartan, which came on about one o'clock P.M., I had great hopes about ten A.M. that I would be able to partake of a favorite dish expected at that day's dinner, but the fever came and I could scarcely bear to look at it when offered. Hence one of the most important purposes subserved by the employment of these measures which we have detailed as calculated to lower the height of the fever, is this one of enabling the digestive glands to resume their work; and accordingly you will find that in proportion as you succeed with those measures in lessening the pyrexia, even if it last for the brief period of an hour, your patient will cease to vomit the nourishment administered, and begin himself to ask for more. One good indication of the benefit of cold baths, for example, is frequently manifested in the natural state of the tongue and mouth secretions. Instead of the dry, cracked, bleeding, and brown tongue, and the sordes collected on the teeth and lips, which are so often described as features of this fever, I have frequently seen the tongue, even in severe cases, remain nearly natural during the whole course of the complaint; thus saving the patient the exquisite distress occasioned by attempts at deglutition with a parched and fissured tongue, and which distress is often the chief reason for their objecting to taking either food or medicine. The thickened articulation of these patients is also absent, if due to this cause rather than to degeneration of the lingual muscles themselves. But as we must

have more or less fever, and therefore abolition of feeding, notwithstanding the most that we can do by the employment of appetetics, how then are we to assist the weak digestive laboratory so that our patient does not succumb to his prolonged fast of twenty-one or twenty-eight days? In the first place, we must begin by saving the alimentary canal a great deal of its ordinary work, by not giving it anything to reduce to a state of solution first, and hence administer food in a liquid form only. Experience has long taught us this fact, but there has been a want of discrimination, it seems to me, in meeting the next indication, namely, in the choice of the kinds of liquid food. In this country beef-tea flows into typhoid patients, and I may also add, out of them, almost continually. In Germany farinaceous gruels are much more common. But I cannot say that I am partial to the employment of either, except occasionally and in moderate quantities. With regard to beef-tea, I think it is more often the plague of a sick-room than any other benevolent mischief that can be named. It has little of meat about it, except its taste, and frequently not much of that; but, at any rate, at its best estate, it represents not so much concentrated nourishment or power, for it has been proved to have actually fewer nutritious elements in it than the same quantity of beer or porter; all that it possesses is that stimulating flavoring principle which makes a meat diet attractive. Fed upon it alone, however, the healthiest stomach will fain not have another drop of it after the first twenty-four hours. Why, therefore, should not our patient also become sickened by the watchful attention which insists on another dose every fifteen minutes for a whole week? But another, and a serious objection, is that all essences of meat are very prone to rapid fermentation when introduced into the hot digestive tube and mixed with matters there already beginning to ferment. This souring of beef-tea results in the evolution of great quantities of gas, and if the remaining liquid be vomited, its acid taste and properties will cause inflammation of the throat and mouth. I am sure, from repeated observations in cases of peritonitis, where we have great paralysis of digestive power, as well as in typhoid fever, that we can avoid the tympanitis characteristic of these affections, almost entirely in typhoid, and very often in peritonitis, by exchanging the administration of beef-tea for the food I am about to advocate; and hence I would advise your reserving meat juices only for those cases of typhoid where temporary stimulation is needed, such as in sudden cardiac paralysis, when, instead of beef-tea, you should administer the juice of meat, expressed by a lemon-squeezer out of pieces of steak, broiled just enough to start the flow of the juice from the fibres, and then have this well salted to prevent its too rapid fermentation.

Gruels are much more nourishing in the long run than meat broths, but still their elements represent only a part of the food of the body, and starvation is as surely the result of a restriction to them alone as in the case of the preceding article.

Far superior to either of these in its nutritive value and in its digestibility, is that liquid prepared originally for the alimentary canal before it is old enough to dissolve any solid food, namely, milk. First, as to nutritive value, there is nothing absent from milk which the system needs, while in all our sick-room preparations there are invariably some deficiencies, and generally, lackings of what is essential to continued life. The bones waste away remarkably in typhoid fever; what is there in beef-tea or gruel for them? The nervous tissue rapidly loses bulk also; where in these articles is there the fat which this more than any other

tissue needs, except the utterly indigestible boiled fat of beef-tea, which turns into caustic butyric acid in the bowels? But milk has been aptly defined as fluid flesh and bones together; still better may we add, soluble nervous matter, for it is the nervous tissue which grows fastest and most at the age when milk alone is the diet. Now we are met by the objection that milk is a very indigestible article in fever, and among the laity we often find a positive dread of it as if it were poison to the sick. I could never understand how physicians will aim by various measures to make milk digestible to infants who have to live on it; while in fever, if it seems to disagree from a more than infantile weakness of the stomach, they are ready to abandon the only thing in the world which can be relied upon exclusively. If we dilute cow's milk, then add sugar and a little salt, and, lastly, cream, so as to make a child starving because it cannot digest cow's milk pure, digest it when it is thus rendered more like human milk, why should we not try the same with a starving fever patient, rather than exchange this complete food for our confessedly incomplete and clumsy preparations? I can only say in answer, that I have never yet met with a typhoid fever patient who could not take milk, and not only live upon it alone, but also, in marked and impressive contrast with those cases which are fed on slops, be found at the termination of the disease with muscles and tissues still nourished enough to cause surprise even to the patient's friends. In order to make milk digestible you should remember that the chief difficulty in the way is its casein, and therefore you should aim to reduce its proportion by dilution with one-half or one-third of lime-water. The alkali in lime-water is a great assistant to the digestion of casein, for reasons too long for us here to explain, but, in addition, like salt, lime is both an antiseptic and an excellent agent for allaying irritability of the stomach and bowels. I have had patients take as much as six quarts in the twenty-four hours of milk and lime-water for days together, nor do I object to the mere bulk or amount of liquid which this implies, because I do not think that water is other than a need and a benefit to a fever patient, for it is the safest of all diuretics, and in this form I have never found it increase diarrhoea, but rather the opposite.

But you have still remaining a means for completing digestion, which experience leads me to rate as one of our best adjuvants in the task before us. The introduction of artificial solvents, such as pepsin and pancreatin, mark undoubtedly a real advance in therapeutics, but in no conditions does the employment of pepsin seem so much indicated as in the indigestion of fever. In fact I have been surprised with some results from its use, which I was not looking for, namely, that it controls the typhoid diarrhoea better than any agent with which I am acquainted. Repeatedly have I known a severe flux not only diminished but very soon altogether stopped, after commencing with pepsin, and the discharges return to normal consistency. Along with the arrest of the diarrhoea I have found the tympanitis likewise disappear, so that it is rare for me now to have either of these annoyances present in a case of typhoid in private practice, from first to last. This may be due, however, in part, to combining other adjuvants with the pepsin, namely, bismuth and muriatic acid with chlorate of potash. My usual plan is to order a drachm and a half of saccharated pepsin with the same of the subcarbonate of bismuth, to be taken in divided doses through the twenty-four hours, after milk, and three or four times a day fifteen drops of dilute muriatic acid in solution, with ten grains of

chlorate of potash. The acid is prescribed on the "restorative" principle, while the chlorate is supposed to act as a powerful and natural antiseptic. Now there is no necessity to aim for a complete stoppage of the diarrhoea in this fever, for a moderate amount of it may be beneficial in relieving the blood of waste matters. But when it amounts to more than two passages a day it can be nothing else than hurtful. Some physicians, whose minds are still influenced by the decayed theory of elimination, advise not to check the diarrhoea lest you leave accumulated typhoid poison behind; but a nasal catarrh on the same principle ought never to be meddled with, for who knows what it may be draining off? The action of pepsin and bismuth in checking this flux, as well as in dissipating the meteorismus, shows plainly enough that the flux is due to a severe intestinal catarrh, induced by the decomposition of the intestinal contents, as we have before explained; and it is fair to ask how a healthy man could fail to be enfeebled by a looseness of the bowels at all comparable with the common diarrhoea of badly managed typhoid? We must here allude also to another gain from the help obtained by artificial solvents and antiseptics. Inflammation and ulceration of Peyer's patches are to be expected at any rate in this disease; but are these lesions not seriously aggravated by a constant flow of acrid matters over the denuded membrane? I can only answer that tenderness over the caecum on pressure diminishes or disappears so surely by the treatment here recommended, that I cannot but conclude that the ulcerative process itself is diminished or limited by the same means which checks the diarrhoea or flux from the affected intestinal tract. By proper nourishment, in short, and by proper means employed to make that nourishment assimilated rather than transformed into a drastic purgative, you will so change the physiognomy of the later stages of this complaint that you will not need afterwards to learn the falsity of that preposterous popular saying, that one should feed a cold and starve a fever.

The next complication for us to manage, namely,

SELF-POISONING,

begins even earlier in the disease than starvation. During the first week there is usually a rapid diminution in all the excretions, but notably on the part of the kidneys. When this is accompanied also by constipation and a dry skin the dangers of the patient are much increased, and these cases are much more apt to have a subsequent prolonged and severe course of fever. As already referred to, it is not unlikely that the retention of decomposition products in the blood, at this stage, favors the reproduction of the fever virus itself so as to explain the increased severity of the after-symptoms. We are, therefore, called upon to help the embarrassed excreting glands by a judicious employment of the eliminatives, and there is a great deal of room for choice here in the particular agents which we should select for this purpose.

The first, and most natural avenue for elimination of retained matters in the blood is by the bowels, and in the beginning of the disease we need not fear the effects of the proper kind of cathartics towards inducing a too free diarrhoea. There is only one cathartic, however, which I would advise you to employ in fevers, and that is calomel. Its action is not only mild in all fevers, even with those who at other times are apt to be considerably affected by it, but besides operating on the bowels, it seems to increase other glandular secretions at the same time, increasing the flow of urine and moistening the skin. You should give it in

doses of from twenty to thirty grains at bedtime some time during the first week. This will usually start the discharges from the bowels pretty freely for two days, when they subside again; whereupon on the fourth day I would advise another similar dose, after which no more will be needed as a rule. Should a diarrhœa of any amount be excited by these doses, it can easily be checked by a tablespoonful of paregoric with fifteen drops of dilute nitric acid. We may speak with some confidence of the beneficial effects of calomel laxatives at this stage of the complaint, because comparative statistics on a large scale by Traube, Wunderlich, Liebermeister, and many others, both German and English authorities, concur in showing a diminished percentage of mortality in those so treated in distinction from those without calomel. All observers also agree that in a considerable proportion of cases the subsequent fever seems to run a shorter course, because a much greater number of cases of the fever terminating in the third week are to be found in those who have begun treatment with calomel. Some authorities, therefore, believe that calomel exerts a specific influence on typhoid, but I am not inclined to accept this view, because, for calomel to act as a specific it should remain in the system and not pass out by the bowels, and hence I regard its beneficial action to be due simply to its being the best cathartic that can be chosen. Iodine also is very highly spoken of by many authorities for modifying the severity of typhoid, but I have no experience myself in its use. It is usually given in the form of iodine, one part, iodide potass., two parts, and ten parts of water. Dose, three or four drops in a glass of water, every two hours. It very rarely causes any symptoms of iodism, does not aggravate the diarrhœa, and does seem to increase the secretion of the kidneys as well as those of the mouth. It should be given for the whole course of the fever unless it seems to occasion some direct symptoms of its own action.

The free use of water, as we intimated before, is to be recommended on the ground of its being an excellent eliminative, as well as urgently desired by every patient with a hot and dry skin.

This leads me to speak of a measure which I adopt in every case of severe fever of any type, but notably in the exanthemata—and that is, general inunction of the body several times a day either with simple olive-oil or with the lin. aq. calcis, composed of equal parts of olive-oil and lime-water. This is one of the oldest means of therapeutics, and the longer I employ it the more I am satisfied that it confers several peculiar and positive benefits; but notably in those complaints in which the skin itself becomes severely inflamed, as in small-pox and scarlatina. But its advantages in other fevers also are not slight. In the first place, it greatly allays the irritability of the surface nerves, which is such a source of restlessness and shifting of the position in fevers. It calms the nervous centres themselves when disturbed by a too constant transmission of external impressions by the excited peripheral nerves, and hence is no mean adjuvant towards procuring sleep. By relieving the tension of the skin also, it disposes to a gentle perspiration, and to that fact I attribute the still further advantage which is undoubtedly often gained by it, namely, of lowering the temperature of the body. You will frequently note a fall of from half a degree to a full degree in the thermometer under the tongue, half an hour after a general oiling, and which therefore cannot be ascribed to a mere cooling of the surface by exposure. Another effect which I have noticed is, that it relieves thirst, which I would ascribe to its restoring a function of the skin,

which enables it to add water to the system when needed, as well as to abstract it when the circulation is too full, and the arrest of which function I regard to be the cause of the thirst always present when the skin is rendered dry either by fever or by the tension of general anasarca. In every case of typhoid, therefore, I direct that the patient be rubbed with oil by the palm of the hand three times a day, and oftener if there be great restlessness or the skin be very hot, and the attendants very soon perceive the use of persevering in the applications on noting the patient often coming out of his delirium during its performance. By this means also, the vitality of the skin is maintained in those parts where you are liable to have bed-sores, so that you will rarely be troubled with this unpleasant complication.

THE RUNNING COLD-WATER BED.

A NEW METHOD OF REDUCING TEMPERATURE.

By A. D. FELTON, M.D.,

SYRACUSE, N. Y.

THE direct application of cold for the reduction of temperature, by means of the bath, wet pack, etc., is authorized and recommended by such authority that we need not expatiate upon its advantages. Its disadvantages in private practice are apparent, viz., popular prejudice; for if your patient unfortunately dies, that hard master, public opinion, condemns the doctor for his foolhardiness in "driving the fever in;" the difficulty of finding the necessary appliances for dipping the patient into cold water, or obtaining competent persons to apply the wet pack, renders it necessary that the physician give his personal attention, and then, if the temperature having satisfactorily diminished the first few minutes of the pack, obstinately persists in rising until it is as high or higher than when he commenced, half an hour previous, the patient passing into a nervous chill, as ours did, he will surely sympathize with us in our disgust. However, later in the day the temperature had decidedly fallen, and we thought better of the cold application, but were unwilling to repeat the operation.

We felt that our patient, in the fourth week of typhoid fever, was rapidly being destroyed with a constantly increasing temperature of $103\frac{1}{2}^{\circ}$ to 104° , accompanied by unpleasant brain symptoms. In our emergency we constructed from a rubber air-mattress a water-bed, with inlet and outlet at opposite ends, to which we coupled a rubber hose, one pipe being attached to the city water-works, controlled by a stop-cock, and the outlet conveying the water from the house. (In absence of the street hydrant, a barrel, at the proper elevation to act as a reservoir, will answer the same purpose.)

At eleven A.M., when the patient's temperature was $104\frac{1}{2}^{\circ}$, we laid him upon the improvised bed, with a blanket between him and the rubber, and a stream of water at 68° running through the bed. In half an hour our bed unfortunately burst, and the patient was of necessity removed; but his temperature continued to descend until ten P.M., when it was $103\frac{1}{2}^{\circ}$, the lowest point reached in four days, except immediately

following the wet pack. At nine the following morning, the temperature was still at $103\frac{1}{2}^{\circ}$, but soon rose to $103\frac{3}{4}^{\circ}$. In the meantime, having repaired our bed, he was again placed upon it, and remained for six hours, when, fearing to trust the nurse for the night, he was removed at nine p.m. Seven hours afterwards, his temperature was 102° , one and a half degrees less than when he was put upon the bed the previous day, and half a degree less than it had been at any time in seven days. In five hours the thermometer indicated $103\frac{1}{4}^{\circ}$, and he was replaced upon the bed, and, with three exceptions, his temperature has not since been allowed to pass 103° , and then through negligence in not changing the water.

At the time of writing, my patient has lain upon the bed constantly for eighteen days, and until within eight days, when the fever began to subside and convalescence was declared, the water was renewed about every five hours.

By frequently changing the patient's position, thereby presenting a fresh surface to the cool bed, regulating the number of blankets over and under him, and controlling the current of water as his sensations and thermometer demanded, we were delighted to find that, while he enjoyed all the comforts and advantages of the water-bed without becoming chilled or exhausted, we could satisfactorily restrain his temperature within reasonable bounds, 102° to $102\frac{1}{2}^{\circ}$, or from one to two and a half degrees lower than previous to using the bed, and that in proportion as the temperature was allowed to approach or pass 103° his respiration and pulse were quickened, the latter becoming irregular and weak, the brows knit, the tongue and jaw trembled, muscular tremor and subsultus tendinum occurred, and delirium increased.

We cannot forbear mentioning the effect of the water-bed upon a would-be bed-sore. In the space of a week all signs of soreness had disappeared, and our patient is loud in his declarations of praise for the comfort of the ever soft bed, with cool cushions for every bone.

It is the opinion of myself and able counsel, Drs. Alfred Mercer and Henry D. Didama, who kindly sustained us in our departure from the customary treatment of fevers, that, in this individual case, we obviated the tendency to death by restraining the temperature with the direct application of cold.

While using this bed the head should be correspondingly cooled by the ice-bag or water-pillow, frequently changed, and the feet warmed if necessary, as with other cold applications. I believe a blanket will usually be required between the patient and bed, and there should be two or three thicknesses under his feet and legs; for a continued temperature of 60° or 70° , directly applied, cannot be constantly endured with comfort, but is agreeably modified by the blanket.

In demonstration of the potency of our bed for the abstraction of heat: when the temperature of the atmosphere was 62° , hydrant water 68° , the water in the bed, after remaining unchanged seven hours was 79° , an increase of seventeen degrees over that of the atmosphere, and eleven degrees above the hydrant water; therefore, our patient has imparted eleven degrees of heat to a barrel of water in seven hours, and his temperature is still $102\frac{1}{4}^{\circ}$. What would it have been without the cold application?

At another time, when the temperature of the atmosphere and hydrant water were alike, the bed was warmed nine degrees in twelve hours, although there were three blankets between it and the patient.

Our water-bed should be supplied with a stopcock at each end, adapted for coupling hose, and be constructed to lie flat and steady, like the air-mattress,

and not like the ordinary water-bed, which a light touch unpleasantly teeters. Other than the advantages it may possess in private practice, in fancy we picture hospital wards supplied with running-water beds, either hot or cold, as the case demands, comfortable, health-promoting, free from vermin, always made, delighting the patient and physician, and easily managed by an intelligent nurse.

SYRACUSE, N. Y., Sept. 22, 1875.

THE "MULTIPLE WEDGE PRINCIPLE," APPLIED TO THE "CONTINUOUS METHOD" OF DILATATION OF STRICTURE OF THE URETHRA.

By JOHN S. COLEMAN, M.D.,

AUGUSTA, GA.

On the 7th of September, 1875, Mr. W., of S. Ca., applied to me for treatment for a stricture of fifteen years' duration. He has frequently suffered from retention, and oftentimes has had to resort to pressure, *i.e.*, to lie prone across a log, to expel the contents of his bladder. Upon examination I find a stricture in the bulbous portion of the urethra, about half an inch in length, dense, and resisting in its nature. I introduced one of Gemrig's small elastic bougies, "made from the intestines of the silk-worm," and tied it in position.

8th.—Some slight febrile disturbance, which readily yielded to a saline purgative and the usual quantity of quinine, *viz.*, 20 grains daily.

11th.—On removing the bougie, which had now been tied in for eight days, I was surprised to find that the stricture had not yielded in the slightest degree, and that I was unable to introduce the smallest gum-elastic catheter used by Sir Henry Thompson.

12th.—I to-day was again enabled to introduce a No. 2 of Gemrig's scale.

15th.—I now determined to apply the "Multiple Wedge Principle" to the "continuous method" of dilatation, and with that view passed No. 1 down by the side of No. 2, and tied it there.

18th.—I introduced to-day No. 4 of Gemrig's scale by the side of the two already in position.

22d.—Two of Gemrig's No. 1 were now passed along the grooves formed by the instruments in the canal.

As I now felt confident that I could use a good-sized catheter, I removed the five bougies, three of which were thickly encrusted with calcareous matter, and introduced a No. 5 bulbous pointed.

25th.—I removed the No. 5 catheter, and tied in a No. 10 conical English scale; this was allowed to remain until the 27th, when I readily introduced a No. 23 steel bougie of Gemrig's scale, the latter corresponding to No. 13 English scale.

I am daily more and more convinced of the superiority of this over all other methods of treating stricture of the urethra, and hope that my professional brethren will give it a trial.

My continued experience in the treatment of stricture corroborates the following language used by Sir Henry Thompson in his work on the urinary organs, p. 26, 11th and 12th lines from the top. The italics are mine: "*First and foremost, dilatation—dilatation always—dilatation without exception, whenever it will succeed.*"

THE YELLOW SKIN OF ANGLO-INDIANS is said by Dr. Henderson to arise from the constant use of curry, which he says is colored with turmeric. He says that turmeric is such a powerful dye that it will in a short time stain even the bones.

Progress of Medical Science.

AFFECTIONS OF THE TONGUE [WHICH RESEMBLE THOSE OF TERTIARY SYPHILIS.—Dr. Charles Schwartz has furnished a résumé of a lecture by Prof. Alfred Fournier, in which he specifies the diseases of the tongue which may be confounded with the later syphilitic affections of that organ, and points out the features of a differential diagnosis. First we have the glossitis due to the constant friction of the tongue against the sharp or broken edge of a tooth. It is characterized by a hard nucleus, resulting from chronic inflammation and erosion, which ultimately is the seat of positive ulceration. It is to be distinguished from an ulcerating syphilide, with which it is very frequently confounded, by discovering the tooth which has caused the ulceration, and by the fact that filing or removing the tooth will cure the ulcer. Secondly, we have the glossitis due to the long continued and excessive use of tobacco, which is marked by the following features, viz.: a mammillated irregular surface, as it were, tuberculated on the edges, the middle covered with a whitish pellicle, which is furrowed and striated in every direction; some induration, especially in the anterior half or third, with erosions or actual ulcers at various points. These latter, which are of chief interest to us, are sometimes quite small and superficial, but at others are more excavated, reach the size of an almond, with an indurated base, often red or yellowish, and irritated. When possessing these latter characters it may be difficult to distinguish from a syphilitic ulceration, unless we pay attention to the history, which will be that of excessive and prolonged use of tobacco; to the chronicity of the affection; and also, to the co-existence of other lesions of the buccal mucous membrane, viz., the opalescent patches on the tongue or cheeks, near the angles of the mouth, which are pathognomonic of the use of tobacco. These look as if collodion had been applied, or nitrate of silver. It is by no means rare, however, for these lesions to co-exist with those of tertiary syphilis, and then a differential diagnosis is practically impossible, and moreover, the combination of diseases is found extremely rebellious to treatment, and the source of great suffering. Thirdly, Tubercular glossitis is associated with a phthisical history and symptoms identical with those of laryngeal phthisis. There are ulcerations, especially of the tongue, closely resembling the syphilitic. The differentiation is to be made from a careful physical examination of the patient, and from the fact of the rebellious nature of these lesions, while those which are syphilitic yield readily to specific treatment. Fourthly, The most important differentiation to make is that from canceroid of the tongue, especially when the stage of ulceration has been reached. Canceroid, he believes, is sometimes hereditary, and is more likely to be observed late in life, especially between fifty and sixty, while the syphilitic lesions are seen at an earlier age. The following points are important. Canceroid is a tumor with an ulcerated surface, it is true, but with a well-defined indurated base, much more marked than in the gummata, which are purely ulcers without tumor. Cancer, again, is unilateral, called *azygos* by Ricord. Its ulcer is more fungous, more ready to bleed, less gray, has less of a core, is less sharply cut, has more granulations. It has a more fetid, ichorous discharge, and is more painful. Again, an excellent

diagnostic sign, when present, is the occurrence of ganglionic engorgement in the later stage of the canceroid, while it is absent in the gummata. Finally, the therapeutic proof may settle the question of syphilis or not, when other tests have left us still in doubt.—*Gaz. hebdomadaire*, Oct. 23, 1874.

A NEW MODE OF TREATING STRICTURES OF THE LARYNX.—In a recent lecture Dr. Michael Grossman, of Vienna, gave an account of a method practised by Schrötter for dilating strictures of the larynx and maintaining the dilatation. The cicatricial contraction or the swelling of the mucous and submucous tissues necessitating such treatment is apt to follow typhoid fever, variola, scarlatina, and especially syphilis. The author has been astonished to observe how great a degree of constriction will often be reached before suffocation appears to be imminent, and attributes it to the tolerance due to the slow progress of the trouble. He states that about one year and a half ago Schrötter began to treat these cases by first performing tracheotomy, and then passing elastic catheters through the larynx and drawing them out through the wound. The accompanying pain, the tendency of the wound to contract, and the impossibility of leaving the instrument long enough *in situ*, were serious objections to this plan. His next plan consisted in the use of a catheter, the extremity ending in a knob or button. The tracheotomy tube was first withdrawn, and then the catheter was introduced through the strictured larynx. It then appears that the tube was reintroduced (?) and the extremity of the catheter made to enter the fenestrum on the upper surface. Suitable forceps were then passed into the tube, the catheter grasped by the extremity, and thus firmly fixed. This instrument was left in position several hours, but it prevented the patient from taking anything but the most liquid nourishment, and it could not be borne during sleep. Schrötter then devised a series of small extremity cylinders, made first of hard rubber and then of tin, and about an inch and a half long. These have a brass stem running through them lengthwise, and end in an eye at one end and in a knob at the other. In using them a strong thread, fastened to the eye, is passed through a conductor shaped like a catheter, and drawn tight, so that the cylinder is brought up to the extremity of the instrument. After oiling, the cylinder is then, by the aid of the laryngoscope, pressed down and lodged in the larynx while the knob is seized by the forceps, as in the method last described. The conductor is now withdrawn, and the thread hangs from the mouth and can be fastened anywhere out of the way, as it gives no inconvenience. The little cylinders may be removed or changed once or twice in a day. They act partly by their weight. The first ones used were round. Schrötter has also devised a dilator, working with a screw, which can be introduced into the larynx either from above or below, according to the curve of the handle. Dr. Grossmann finds the galvano-caustic a very valuable adjunct in the treatment of these cases, and says that patients do not find its application so painful as that of caustic potash, or even nitrate of silver. As a further means of keeping up the treatment, even when the tracheal fistula has been allowed to heal, Schrötter employs hard rubber catheters of different sizes, with open extremities, through which the patient can easily breathe, and which he readily learns to introduce himself. In some cases early treatment by these methods has obviated the necessity for tracheotomy.—*Berliner klin. Woeh.*, June 23, 1875.

ON DISINFECTION OF THE SOIL.—Dr. Jos. von Fodor, professor of hygiene at Buda-Pesth, has been making some experiments on the disinfection of the soil and the gases contained in it. Although not yet complete, he gives the results he has so far obtained. He argues that the diffusion of typhoid, cholera and other infectious diseases stands in direct causal relation to the pollution of the soil; and further, that the gases contained in such soil are the active agents by which our dwellings and our own systems are infected. The degree of contamination of the soil varies in different cities, streets, and houses, as indicated by the foci from which these infectious diseases spread. Thus, he argues that if we can remove or render harmless the impurities of the soil in such foci, we have gained an important hygienic advantage. As the ground beneath our houses cannot be removed, he conceived the idea of destroying the decomposing substances it contains by passing gaseous disinfectants through it. His first experiments were with carbolic acid. He filled a glass vessel, about two inches in diameter and one foot high, with moist, sandy soil, and forced through it from below air saturated at 72° F., with carbolic acid. Although this was continued for several days, he was utterly unable to saturate this thin stratum of earth with the carbolic acid, the air as it came out at the top being quite free from smell. He was equally unsuccessful with sulphurous acid. With chlorine, however, he was successful. A weak current of this gas easily passed through earth placed in a vessel similar to the last, though forty inches high. He also found that it acted equally well when tried on a larger scale, and with earth which had been rendered foul and offensive with a solution of sugar and stale urine, so that air which escaped was heavily charged with carbonic acid. Finally, he sank some iron pipes in the ground, one in the middle and others at various distances from it, and to various depths of from twenty to eighty inches. He then forced chlorine, by means of a bellows, into the middle pipe, and tested the air which came up through the others. The result was that he obtained evidence of the gas in tubes forty inches from the central one, and reaching to a depth of sixty inches, the latter being sunk a little over sixty inches.—*Allg. Med. Cent. Zeit.*, August 18, 1875.

NEUROSES DEPENDENT ON MALARIAL DISEASE.—Dr. Valentine Kiparsky, of Moscow, reports several cases which fell under his observation while in a highly malarious district of the Caucasus, and which he regards as malignant neuroses of the heart, dependent on malaria. They all occurred within a short time, striking with lightning-like rapidity, and were marked by loss of consciousness and cessation of pulse and respiration—an apparent death—which became real from paralysis of the heart, unless instant aid were at hand. All four of the cases occurred in women who were menstruating. There was slight abdominal pain and quickening of the pulse, followed by instantaneous death in three of them, without other symptoms worthy of notice. In the fourth case, the immediate employment by restoratives—heat and brandy—brought back the pulse and consciousness in a few moments. Within a very few minutes more the patient was in a high fever, 106.2° F. After two large doses of quinine, recovery was prompt and complete. In the one case in which an autopsy was obtained, the heart was found flabby, in the condition of diastole, the right heart and venous system gorged with blood. Nothing else abnormal. Dr. Kiparsky's interpretation of these phenomena is that they were cases of febris algida, with collapse or

syncope from weakness of the heart at the beginning of the cold stage, that organ not being equal to the task imposed upon it by the excessive contraction of the vessels of the skin.—*Allg. Med. Cent. Zeit.*, August 21, 1875.

THE INOCULATION OF VARICELLA.—Prof. Steiner reports his experience in ten cases in which he has practised inoculation of the clear watery fluid taken from freshly developed varicella vesicles. Eight of the ten succeeded, that is, they were followed by the development of varicella, and never of variola. Of these, five had been vaccinated, and three not. In all, the duration of what he calls the stage of inoculation lasted eight days. Four times the eruption appeared without any prodromata. The highest temperature, as a rule, coincided with the eruption; the defervescence was rapid and complete. The course observed after the inoculation was ordinarily the following: On the third day nothing was to be seen at the point of insertion; on the fourth a gradually increasing febrile movement began, with distinct evening exacerbations and morning remissions. There was decided reddening of the mucous membrane of the mouth and throat before the appearance of the eruption. This followed on the eighth day, and the disease then ran its ordinary course.—*Rundschau*, Aug., 1875, from *Wien Med. Woch.*, 16, 1875.

ADAMS'S OPERATION FOR SUBCUTANEOUS DIVISION OF THE NECK OF THE FEMUR, PERFORMED ON BOTH SIDES FOR STRAIGHT ANCHYLOSIS.—Mr. Lund, of Manchester, reports a case in which both hips were ankylosed in the straight position, so that the patient was unable to sit down. Subcutaneous division of the neck was performed first on the left side, and twelve weeks afterwards on the right. The results were very satisfactory, excellent power of motion being acquired in both hips. The patient could support the weight of the body on either leg, and was in all respects greatly improved. Mr. Adams stated that his own results had never been so good; as a rule, the cases to be operated upon were, beginning with the best, rheumatic, pyæmic, traumatic, and scorbutic; though the last he would not operate upon.—*Trans. of the Brit. Med. Ass.*—*Brit. Med. Journal*, Aug. 28, 1875.

TO REMOVE STAINS PRODUCED BY THE NITRATE OF SILVER.—A few centigrammes of metallic iodine are placed in a saucer, to which a few drops of ammonia are added. Then, by means of a brush, or simply with the finger, the solution is applied to the stains. However old or extensive the stains may be, they disappear immediately. It is important to destroy the mixture afterwards, since it is nothing more nor less than the iodide of nitrogen, which when dry is an explosive body. This procedure is decidedly superior and more prompt in its action than the application of a solution of iodine, or of the cyanide of potassium, without possessing the disadvantages of the latter.—*L'Abcille Medicale*.—*Le Bordeaux Médicale*, August, 1875.

TREATMENT OF INTERNAL OCCLUSION OF THE INTESTINES BY ELECTRICITY.—Dr. Fleuriot, in view of certain observations which he has made, more particularly in a case which he observed in the hospital at Brest, advises the employment of electricity to overcome internal strangulations of the intestine; he has used for this purpose GaiFFE's apparatus, and places one of the electrodes at the anus or within the rectum, and the other upon the abdomen.—*Thèse de Paris*, 1875.—*Gaz. Méd. de Paris*, Aug. 21, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

GEORGE F. SHRADY, A.M., M.D., Editor

PUBLISHED BY

W.M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, October 23, 1875.

HOMŒOPATHY IN THE UNIVERSITY OF MICHIGAN.

The subject of homœopathy in the Michigan University still attracts considerable attention. As might have been expected, the discussion of the merits of the question has been animated from the start, and many of the disputants have been strongly imbued with a radicalism for one side or the other. At one time the faculty of the medical department of that institution was in such imminent danger of being sacrificed on the altar of an expediency, that any hope of their being able to explain their position appeared to the majority of the profession utterly futile. With this majority, as one of our contemporaries has said, "the very mention of the word (homœopathy) was almost like touching a spark to gunpowder."

As every one knows who has been acquainted with the history of the Michigan University, the homœopathic question has quite a history, dating back almost from the time the institution itself was founded. After being repeatedly defeated, the homœopaths have at last triumphed in getting a foothold in the medical department. It is safe to say, that if this could have been prevented, the faculty of medicine would have spared no pains, nor shrunk from any required work which conscientious opposition could force upon them. We are satisfied, from what we know of the history of the whole affair, that this assertion can be supported by facts.

To read, however, some of the criticisms which have appeared from the correspondents in some of the journals, it would seem that the said faculty are not only to blame for everything that has occurred, but are so wanting in ordinary orthodoxy as to bring upon their school the discipline of the American Medical Association, in the way of ceasing to recognize their pupils.

Accepting the fact of a homœopathic graft upon the college, the question at once arose whether or not it was best for the faculty to resign. To those who followed

the impulse of prejudice rather than the voice of reason, the answer seemed obvious. There appeared to be no other way of getting rid of the graft than by cutting down the tree. After calmly viewing the situation, very many discovered that they had an affection for the University, and were determined not to sacrifice it. Then reason began to prevail, and the preparation was made for a calm hearing of the statement of the faculty. The principal object of this statement is to show that the best interests of the institution demand that the present faculty should remain where it is. Impartially judging all the circumstances of the case, it is our opinion, as before intimated, that they have the best side of the argument. As we understand it, there is no attempt to justify the action of the Regents; only a judicious acknowledgment of the fact that the governing power of the University had a right to do as it pleased. The faculty, then, do not endorse the measure, but are willing to make the most of the association that is forced upon them.

It might have been much better to have had an entirely separate department for the homœopaths, and this suggestion we made at the very commencement of the trouble; but for the time being this is out of the question. And after all, although it is not easy to admit it from the present standpoint of general professional opinion, it is perhaps best that it is so. The regular profession has to meet the issue one time or another, and all other things being equal, the sooner the better. We are heartily wearied of the cry of martyrdom on the part of the Hahnemannites, and the more liberal we are towards them the sooner will the question of their superiority of intelligence, their honesty of purpose, and their extraordinary skill in the treatment of disease be forever settled. Their present position in regard to the university gives them all the opportunities which they may reasonably ask for working out their own salvation. They have, if not in fact, at least in name, the association with a well established and reputable school of regular medicine, with all the privileges of instruction which they may desire, and the extra opportunity of special teaching in the peculiar doctrines of their own faith. If the special beliefs of homœopathy can be best combated by truth and light, the "Department of Medicine and Surgery" have every advantage of not only maintaining their ground, but of vanquishing the intruders. The more we concede to them in the beginning, the more triumphant will be our victory in the end. In this view it is hardly fair to assume that the university is giving comfort to the enemy.

We think that the faculty, far from being condemned for the course taken, should be upheld by every liberal-minded professional man, and should be encouraged by every impartial searcher after truth. They are not placed in any position which will compromise their honor, and although disagreeable associations may be forced upon them, it is their duty to

make the most of the situation, and calmly await results. They can assume no responsibility in granting homœopathic diplomas, as their names do not appear thereon, nor do they pretend to recommend any candidate for such distinctions. It is true each one of the regular professors examines these candidates in his respective branch, and certifies thereto; but this is all. Although it may be assumed, and with considerable truth, that the homœopathic college may prosper by borrowed light, yet the homœopathic graduate from that school, practically speaking, receives no credit for having passed the examination of any but the two homœopathic professors.

SPECIAL MEDICAL ADVERTISING.

WE are quite amused to hear from some of our country contemporaries how much the progress of medicine in New York is due to a few so-called shining lights, and how dependent it is upon them for its reputation as a medical centre. The celebrity of these great men is mainly due to the New York correspondents of the journals in question, who, from all appearances, have very little to write about. In these letters we notice one or two gentlemen in particular who figure quite prominently as acknowledged leaders of medical thought here. We can hardly account for this strange unanimity of opinion on the part of these correspondents in any other way than some unusual facilities which have been disinterestedly forced upon them for forming such opinions. At best it is a strange coincidence, and if it were not that medical advertising is getting respectable, we should question their intentions.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 7, 1875.

DR. S. S. PURPLE, PRESIDENT, in the Chair.

AFTER the reading of the minutes of the last stated meeting, the President announced the death of Dr. Ernst Krackowizer and Dr. Cyrus Weeks, and upon motion appointed Drs. Gordon Buck and Jacobi as a committee on resolutions upon the death of Dr. Krackowizer, and Drs. Finnell and Anderson as a like committee upon the death of Dr. Weeks.

DR. JACOBI was also appointed as memorialist upon Dr. K., and Dr. Finnell the same upon Dr. Weeks.

DR. LYMAN, of Chenango Co., was introduced to the Academy. The committee upon admissions reported the following names: Drs. W. B. White, J. D. Bryant, W. G. Wylie and Alex. Hadden.

MR. JOHN ERIC ERICHSEN, of London, was elected corresponding fellow of the Academy.

PREPARATORY to discussion, Dr. Isaac E. Taylor gave a synopsis of the paper which he had read at the previous meeting, upon the best method of managing

CASES OF LABOR WITH CONTRACTED PELVIS.

Discussion was not extended, but remarks were made

by Drs. Peaslee and Hanks. Dr. Peaslee regarded the position taken by Dr. Taylor as incontrovertible, especially when we consider the results of treatment; and Dr. Hanks related the history of a case bearing upon the subject in question.

DR. ELSBERG next proceeded to the reading of his paper upon

PNEUMATOMETRY,

as a new means of diagnosis in diseases of the respiratory organs. This is simply a method of measuring inspiratory and expiratory force, and its value in disease is that by it both inspiration and expiration can be measured exactly, which enables the observer to see precisely what the variations from the healthy standard are. The instrument consists of a simple glass tube bent upon itself and fastened in front of a graduated metallic scale. This tube is about half filled with mercury, and secured to the scale by a screw when the level of the mercury corresponds to zero. To one limb of the tube, the other being sealed, is attached a piece of rubber tubing, which ends in either nostril pieces or a mouth-piece or an oro-nasal mask. Blowing into the rubber tube depresses the mercury in one limb of the glass tube, and causes it to rise in the opposite limb, and the reverse takes place when an inspiration is made. The difference between the two is noted, and gives the difference between inspiration and expiration, and the variation of both or either from the healthy standard.

It was claimed that by means of this instrument pulmonary emphysema can be detected in its incipient stages even before any actual subjective disturbances exist. Observations were also given which had been made with regard to asthma, bronchitis, pulmonary phthisis, diseases of the circulatory organs, abdominal organs, etc., etc. The pneumatometer was presented not as an invariable guide in diagnosis, but simply as an additional aid in the investigation of certain doubtful cases.

NEW YORK MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

Stated Meeting, October 8, 1875.

DR. E. R. PEASLEE, PRESIDENT, in the Chair.

THE DANGER OF TRANSMITTING SYPHILIS FROM NURSING TO NURSE, AND VICE VERSA, IN PUBLIC INSTITUTIONS.

DR. R. W. TAYLOR read an interesting paper upon the above subject, in which he clearly elucidated the fact that such a calamity has occurred, and therefore may be repeated unless more scrutinizing precautions are taken in the way of prevention. The study of this subject is interesting and peculiar for various reasons, but particularly because the origin of the malady is wholly unassociated with the sexual act. It is important for the reason that the buccal lesions in syphilis, notably the mucous patches, are prolific sources from which syphilis may be transmitted, and are of very frequent occurrence; reaching as high as 70 per cent. in hereditary cases. The methods of contagion are: (1) an infant having mucous patches is nursed by a healthy woman; the morbid secretions are deposited upon the nipples, the system becomes infected with syphilis, and now having the initial lesion developed upon this site the secondary manifestations follow; (2) a woman who has syphilitic chancres upon the breast and nipples transmits the poison to a child which has hitherto

been unaffected by the disease. The greatest dangers of such transmissions exists in hospitals and asylums, where large numbers of children are congregated and nurses employed to nurse them, and the importance of thorough inquiry into the condition of each child and nurse cannot be over-estimated.

As a text for the study and illustration of the question, Dr. Taylor gave a very minute and detailed history of a case which had fallen under his observation in consultation with Dr. Loring, in which a healthy woman in one of our lying-in asylums was called upon to nurse two children that subsequently died from the effects of syphilis. When he saw her a well developed chancre was present upon the left nipple, which was the one she had given to these children, reserving the right breast *exclusively* for her own child, that was without blemish.

The woman subsequently suffered from secondary lesions, such as roseola, hyperemia of the pharynx, typical adenopathy in the axilla, etc., etc. The period from the time of nursing the first child to the appearance of the initial lesion upon the woman's nipple was about fifty days, and from forty-two to forty-seven days after nursing the second child. Now the period of incubation for syphilis has been established at from seven to ten days as the shortest and seventy days as the longest, so that although the time which elapsed after the exposure of this woman's breast to the mouth of a syphilitic child was quite long before the initial lesion appeared, yet it was far within the limits of impossibility.

Inasmuch as about seventy per cent. of the cases of hereditary syphilis present buccal lesions, the mode of transmission from nursing to nurse cannot be too fully appreciated and provided against. There are certain difficulties in the way of prevention which a moment's reflection will make apparent. First, it is a matter of great difficulty to determine in very many cases whether the sore mouth which may be present is syphilitic or not. If there was nothing but the ordinary mucous patch to be recognized no special difficulty would be realized, but unfortunately the typical appearances are very often lost, and such sore mouths present only, or almost only, the look of an ordinary stomatitis. On the other hand, nurses may have syphilitic chancres upon their breasts which can be readily recognized, but they *may* receive children to nurse when in the period of incubation of a mammary chancre, or in that stage of its development in which there is simply an abrasion, a pimple, a fissure, or an excoriation. Indeed, these are the appearances of the initial lesion, which are usually overlooked *entirely* by the nurse, being attributed to chafing by the clothes or other agency, and are *liable* to be overlooked by the physician unless the utmost care is exercised. It is these apparently trivial appearances of the primary lesion that may be the precursors of syphilis, and should be most cautiously guarded against.

This leads directly to the question of selecting nurses, and that brings up the history of all the children nursed within the past two months, as well as the history of all those nursed temporarily and their condition; and in addition, the nipples of the nurse should be scrutinized in the closest possible manner. In doubtful cases in the *nursing*, the proper course is to, temporarily at least, nourish the child by bottle-feeding, and in this even the greatest care should be exercised lest the virus be transmitted from one child to another by the utensils employed. For suburban asylums goat nursing was suggested.

After the reading of the paper by Dr. Taylor Dr. F. P. FOSTER exhibited a new

VAGINAL DOUCHE,

which certainly had the appearance of a very valuable and convenient apparatus; for with it vaginal injections can be given without regard to quantity, and without soiling the bed or changing the position of the patient. The instrument consists of a soft rubber cylinder, at the distal extremity of which are a few small openings. To this flexible cylinder is attached a piece of rubber tubing, which permits the entrance of a stream having a greater calibre than the combined calibre of the small openings at the distal extremity, and to this piece of rubber tubing a Davidson's syringe can be attached, or a suspended vessel containing the injecting fluid. When the cylinder has been introduced and the injecting fluid thrown in it becomes distended, fills the vagina, and thus prevents any reflux. The reflux, however, is provided for by a metallic tube which is *within* the flexible cylinder, and has attached to its open mouth the distal end of the cylinder, while to the other end a piece of rubber tubing is attached which conveys it to any convenient vessel.

With this instrument the fluid is prevented from running out over the perineum, which enables the operator to use much warmer water, for instance, than could otherwise be borne, and it also permits the use of injections without wetting the vagina, which to many patients is very desirable. There is a certain ratio between the size of the stream which enters the flexible cylinder and the small openings at the distal extremity, which is necessary to the proper working of the douche. To obtain this ratio has cost much time and numerous experiments, but the doctor will cheerfully furnish it to any one who wishes to secure an instrument if they will call upon him. The thanks of the association were extended to Drs. Taylor and Foster for their interesting communications.

Reviews and Notices of Books.

1. A PRACTICAL TREATISE ON DISEASES OF THE EYE. By ROBERT BRUDENELL CARTER, F.R.C.S.

The author states in the preface that "his aim has been to place before the profession, in a concise and readable form, a general view of the present state of knowledge with regard to the nature and treatment of the more important diseases of the eye"; and it is with great pleasure that we can endorse the work as a most valuable contribution to practical ophthalmology. Mr. Carter never deviates from the end he has in view, and presents the subject in a clear and concise manner, easy of comprehension, and hence the more valuable. The book cannot be called a complete treatise on the subject, for there is no mention made of the important class of diseases relating to the orbit, and in some points of pathology the author has confined himself within too narrow limits. We would especially commend, however, as worthy of high praise, the manner in which the therapeutics of diseases of the eye is elaborated, for here the author is particularly clear and practical, where other writers are unfortunately too often deficient.

The work is divided into fifteen chapters, which the reviewer has thought best to take up in order.

Chapter I. treats of the anatomy and physiology of the eye, and is full enough for the student without be-

ing too finely elaborated, as is the case in Continental text-books; but the author makes a very curious omission, and one or two misstatements. In describing the anterior or external elastic lamina, he calls it Reichert's membrane, but makes no mention of Bowman, whose name has been connected with it from the first; an omission very remarkable in an Englishman. In another place he states that at birth the anterior surface of the iris is invariably blue, and that all infants, even among the dark races, are born with blue eyes, which is certainly not the case. Again, in describing the optic nerves, Mr. Carter regards the question of the complete decussation of nerve-fibres in the chiasm as settled, while, in fact, that opinion is by no means universally accepted.

Chapter II. discusses the method of examining the eye, and is a most excellent one, especially on the subject of refraction and the state of the visual field. The question of the tension, physiological and pathological, of the eyeball is discussed in a few words, and the scale made use of generally in text-books is correctly shown to be useless for purposes of comparison. In speaking of the examination of the media of the eye, the author says that cataract is common among diabetic patients, which we think is too wholesale a statement, for we do not think it is usually met with. Further on he says that a certain kind of degeneration of the retina is almost always associated with the forms of renal disease which produce albuminuria, which, however apparently true in former years, is less so now; for this peculiar retinal degeneration has been seen in patients who were entirely free from renal disease, and so remained for years. This chapter, however, is particularly noticeable for the care with which Mr. Carter distinguishes between *seeing* and *observing*, and for the emphasis with which he insists upon the grand necessity of cultivating powers of observation.

Chapter III. treats of the ophthalmoscope and its application. In it the author claims the honor of constructing the first ophthalmoscope for an Englishman, Mr. Babbage, a fact which is but little known, and not mentioned in any text-book, that we are aware of. The chapter gives a very concise and intelligible account of the principles employed in the use of the ophthalmoscope, and is therefore valuable to the student, but one or two statements need modification or correction. When Mr. Carter asserts that he is not acquainted with a single authenticated instance in which it has been shown that the reflection from the mirror has done harm, we are sure that some of our American ophthalmologists will not agree with him, for some of us have seen grievous results in too frequent or prolonged use of the instrument, especially in the acceleration of a threatening glaucoma. The author, moreover, does not seem to be well acquainted with the ophthalmoscope of Dr. Loring, of this city, for he mentions a modification of it by Dr. Noyes, which we, his fellow-townsmen, have yet to hear of; and he makes no mention of Dr. Loring's own improvements in his instrument, in placing all the lenses in one disk in two cretes, and in covering them from external injury by a narrow metallic band.

In *Chapter IV.* Mr. Carter gives us the principles of ophthalmic therapeutics, which for great practical value is the best in the book, and can be read and re-read with profit. The question of correct diagnosis is intimately blended with the therapeutics, and in the author's manner of going to the bottom of everything, we see much to remind us of the thorough work of the lamented Dr. Anstie. He discusses quite fully the derangements of nervous function, the influence exerted by the fifth nerve on the nutrition of the eyeball, and

especially on what he calls the remote origin of eye-disease. This is a subject of very recent interest, and hence this chapter is of double value. Mr. Carter is a firm believer in the constitutional treatment of inflammatory diseases of the eye, and gives us some valuable practical hints in the proper employment of drugs.

Chapter V. treats of the principles of ophthalmic surgery, in which there are no new hints, but we give the author's own words in regard to the multiplicity of instruments in the surgeon's armamentarium, as follows: "The instruments now living, so to speak, and familiar to us, may be divided into two great classes: the essential, which are the representatives of inventive ingenuity, and the superfluous, which are the representatives of inventive awkwardness. The former class have been contrived by good mechanics, the latter by bad surgeons. The safest man is he who never invented an instrument in his life, but whose daily practice affords evidence that he can use those which have been invented for him by others." Mr. Carter speaks very highly of the use of ether as an anæsthetic, and gives due credit to Dr. B. Joy Jeffries, of Boston, for having been the means of bringing it into more general use in England.

Chapter VI. discusses diseases of the eyelids and lachrymal apparatus, which is too short, and, we think, faulty, at least as far as the latter subject is concerned. In speaking of obstruction of the nasal duct, the author says that experience has taught him, after watching attentively the results of various kinds of practice, that the best treatment, in a great number of instances, is that which is only palliative, and that the best surgery, generally speaking, is to leave the obstruction alone. This we regard as very bad advice and by no means to be followed. There is scarcely a class of diseases in which temporizing does so much harm as in these affections of the nasal duct, and though we perhaps succeed in curing but a small percentage of them by surgical interference, yet we certainly benefit a large number.

In *Chapter VII.* we have an excellent, concise discussion of the more common affections of the conjunctiva, especially of the contagiousness of trachoma and granular ophthalmia in large assemblies of children and adults, and the systematic disinfection of buildings and their contents where such diseases prevail. Mr. Carter very justly protests against the objectionable term "diphtheritic," as applied to cases of conjunctivitis, where the discharge is fibrinous instead of purulent. The disease is certainly not a true diphtheritic deposit on the conjunctiva, a disease wholly unknown in England, and almost as much so in this country, but which is quite prevalent in some parts of Germany among poor children.

In speaking of pterygium, the author regards it as scarcely at all amenable to treatment, for, if removed, the same kind of action is often renewed in the cicatrix, and that a pterygium does no harm unless it extends so far over the cornea as to obstruct vision, and then the best course is to enlarge the pupil by iridectomy. This we regard as bad surgery. A pterygium should always be excised before it has encroached upon the pupil, and it very rarely returns. Iridectomy for such a purpose is not to be recommended.

Chapter VIII. is a good practical discussion of the more important diseases of the cornea. In speaking of vascular keratitis, Mr. Carter points to the probable government of the morbid process by nerve-distribution, and if this view is correct, the practitioner should in every case look beyond the eyes themselves for the inception of the malady, and this we regard as an important point in diagnosis. In all such fine points of

Correspondence.

ELECTROLYTIC TREATMENT OF TUMORS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In an article in THE MEDICAL RECORD of Oct. 2d, a case of recurrent fibroid tumor of the neck is reported, followed by some remarks on the electrolytic treatment of tumors. In connection with the case the author offers two questions for consideration, viz.: "What is the relative value of electrolysis in the treatment of tumors?" and, "May not its use, from the irritation it produces, convert a benign into a malignant growth?" After a few hasty considerations he concludes: 1st. "That electrolysis has only removed a few small, unimportant tumors, and a few small naevi." 2d. "That as a method of treatment which does away with the knife (and one which can be used at times and in places where the knife cannot) it is certainly of value, but even under the *most favorable circumstances* it is an *uncertain* and sometimes even a dangerous remedy." 3d. "That the electric treatment of the tumor in question converted it into a malignant one." 4th. "That electrolysis should *only* be used in the treatment of tumors when they are very small, or are inaccessible to any other method." While electrolytic action has been understood and utilized in surgery more or less for many years, the results that might be expected in a given case were far from definite; now, however, the possibilities and limitations of electro-surgery are measurably clear. We know, for example, that electrolysis will *not* cure cancer, but that it will almost invariably relieve the excessive pain that is so often associated with it. Extirpation of a malignant growth, followed by complete destruction of the underlying tissue by the electrolytic process, is the only feasible method, and the measure of its utility can only be determined by an extended series of observations. The probabilities of occasional success depend upon the truth of the local origin theory of cancer, as so ably set forth by Van der Kolk, Morgan, and others. We know that we cannot *depend* upon it for the dissipation of large, firm tumors, whether benign or malignant, and yet it seems to me that the author of the paper in question concludes hastily and erroneously. It is certainly important that a valuable method of operation, from which so much was expected, and which has in some respects so decidedly disappointed expectation, should be correctly appreciated. The results of cases, he remarks, "show that electrolysis has only removed a few small, unimportant tumors, and a few small naevi."

Few tumors are unimportant to the person whom they afflict, and erectile tumors are often especially annoying. Electrolysis is not only uniformly successful in dissipating them, but, if used with due care, will leave little if any scar to mark their seats. Cystic tumors, as well, yield readily and quickly to electrolysis, notwithstanding the very bold assertion (and which should not have been ventured, excepting it were founded on much experience), "that even under the most favorable circumstances it is an *uncertain* and sometimes a dangerous remedy."

On the contrary, it is, as a rule, a very *certain* remedy—certain in the great majority of tumors to fail, but in a few varieties of growths—two of which I have mentioned—pretty certain to succeed.

The danger from sloughing is also, I am sure, over-estimated. I have seen very little of it, although I admit that in erectile and some other tumors it may occur, if the current is injudiciously used. In scirrhus of the female breast very strong currents are necessary to cause suppuration, and occasionally the most intense currents fail to produce any effect whatever.

In the sarcomatous variety of tumors, however, electrolysis is quickly and almost invariably followed by increase of size, ulceration, and the formation of numerous fungoid growths.

Finally, the single case of fibro-recurrent tumor that constitutes the text of the article under consideration seemed, according to the author, to teach, 1st. "That the electric treatment employed converted it into a malignant growth." 2d. "That electrolysis should only be used in the treatment of tumors where they are very small, or are inaccessible to any other method."

When it is remembered that electrolysis was attempted with the faradic current, an entirely unnecessary and unjustifiable procedure, we can well understand that the irritation was capable of exciting a malignant action. If, however, the idea is conveyed that electrolysis proper (electrolysis with the galvanic current) has any special tendency to convert benign into malignant growths, all experience and experiment disclaim it. I doubt whether sufficient evidence could be adduced to offer a foothold even for such an opinion. The electrolytic action of our ordinary faradic current is for all practical purposes absolutely *nil*, and where tumors have disappeared under its action it has been because of its irritant and not of its chemical effects. It is therefore to be excluded in the consideration of electrolysis.

While it is admitted that the results of electrolytic action are capricious in the treatment of all but a few varieties of growths, it is yet occasionally effective in tumors of considerable size, and notably so in bronchocele and fatty enlargements. Goitres are almost always reduced more or less in size, in not a few instances have disappeared altogether, and in three cases that have fallen under my observation the growths were dissipated by external applications alone. Fatty tumors, as is well known, have disappeared under various forms of irritants, and electro-puncture with the faradic current might possibly avail in some favorable cases. I have never tried it, but among a number of cases treated unsuccessfully by galvano-puncture, I have records of two cases in which it was entirely effective. In one case the growth was the size of a hen's egg, and had existed many years. I recommended removal by the knife, and referred the case to Dr. A. B. Crosby, who saw it with me. No persuasion, however, could induce the patient to submit to any cutting, and therefore galvano-puncture was attempted. Three sances, during none of which was the slightest pain experienced, resulted in a complete and permanent disappearance of the growth.

I cannot therefore subscribe to the validity of the final conclusion, that electrolysis should only be used in the treatment of tumors when they are very small, or are inaccessible to any other method.

Yours truly,

A. D. ROCKWELL, M.D.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I have been a constant reader of THE RECORD for several years past, and have acquired from its pages much information of almost incalculable value. I have been more particularly interested in the articles which have appeared from time to time concerning the therapeutical and surgical use of electricity. Many

of those articles show the writers to have been not only scientific men generally, but also that they were ably posted in the science of electricity in particular; consequently their terms were accurate, their meaning plain, and their contributions highly interesting and instructive.

In your issue of October 2d, I see an interesting report by Dr. Comegys, containing "Some Remarks on the Electrolytic Treatment of Tumors," in which he draws the two following conclusions:

1. This electric treatment converted a recurrent fibroid into a malignant tumor.

2. Electrolysis should only be used in the treatment of tumors when they are very small, or are inaccessible to any other method.

Both of these conclusions may be true and very properly drawn from his premises, and yet not be a fair statement of the value of electrolysis, or the limits of its application.

I have for a long time studied and experimented in its use in the treatment of tumors of nearly every variety. My success, although discouraging at first, has steadily increased as I gained a knowledge of the laws and principles which govern its action. To obtain the most successful results, according to my experience, the following conditions have to be complied with:

1st. None but the uninterrupted galvanic current should be used.

2d. Only the negative should be used in the tumor, the positive to be applied to some other portion of the body, by means of a sponge moistened in warm salt-water.

3d. The needle used should be composed of either platinum or gold.

4th. A current should be used of sufficient intensity to produce a visible decomposition of the tumor, as evidenced by the bubbling out of gas (hydrogen) around the inserted needle.

Tumors that particularly indicate its use, and which it invariably succeeds in discussing, are those of a sanguineous nature, the most numerous of which class are hemorrhoids. With few exceptions, all tumors which are not of a hard, fibrous or cartilaginous nature will readily yield to its disorganizing powers.

Malignant tumors should be completely and thoroughly disorganized. Other tumors generally take on a rapid process of absorption after being partially destroyed by the electrolytic action, and soon disappear.

The great advantages this operation possesses over all others are: the absence of hemorrhage; the *minimum degree of inflammation* by which it is followed; the absence of sloughing, and the *rapidity and kindness with which the wound heals*. When properly performed, it does not produce, neither is it followed by the putrid materials capable of causing septicæmia.

In no case have I ever seen it increase the rapidity of growth, or cause a non-malignant tumor to assume a malignant type. Out of nine cases of malignant tumor, three were cured (and up to this time without any return), four were relieved from pain, and the growth for a long time arrested. In the other two cases, there was no perceptible change, either favorable or otherwise.

I do not claim that electrolysis is advisable in the treatment of all tumors, or even the majority of them; but I do claim, that in those cases for which it is adapted, its merits are incomparably superior to those of any other method.

Respectfully,

F. S. ADAMS, M.D.

SPRINGFIELD, O.

LIGATION OF FUNIS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Tying the placental end of the dissevered funis previous to the expulsion of the placenta is not done to avert *danger* from hemorrhage of that sanguineous mass, but is an act depending upon the estimate a practitioner puts upon the value of neatness in his obstetrical operations. A depleted placenta, previous to its extrusion, is equivalent to a needlessly drenched bed. With proper precautions a retardation of placental expulsion is a circumstance of rare occurrence, as depending upon the retention of its normal allowance of blood.

Dr. A. Rose's strictures of October 9th upon my article on a method of ligating the funis, in THE MEDICAL RECORD of August 28th, 1875, is deprived of its significance as a sound criticism, based upon the presumption of superior anatomical knowledge, when we consider the language used in my article: "Another ring is commonly slipped over the placental end of the funis." The word *commonly* means neither invariably nor of necessity, but means in the *usual order of practice*. The usual practice of constricting the placental end of a cut umbilical cord has for its object, as I supposed, the prevention of a needless escape of blood during a function characterized, at the best, by a great quantity of unpleasant fluids discharged.

Very respectfully,

GEO. BAYLIS, M.D.

37 W. 48TH ST., NEW YORK, October 11th, 1875.

THE INDIA-RUBBER CATHETER.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In your issue of October 2d a correspondent commends the use of the India-rubber catheter in enlarged prostate. I have been using this form of instrument since last spring, and consider it admirable, and worthy to come into general use in all cases where a catheter is required.

The service one has recently rendered me constrains me to address you concerning it.

A man, who was severely injured by a recent boiler explosion, suffered retention of urine. I was called up in the middle of the night, and urgently requested to visit and relieve him. He resided several miles in the country, and I was too tired to visit him if it could well be avoided. Happening to think of the India-rubber catheter, and realizing that no harm could come from its employment by unskilled hands, I gave one to the messenger, with instructions, and he immediately entered the bladder and relieved the patient with it on his return.

It is not safe to entrust an inflexible, or styleted, catheter to hands unskilled in its use. And what surgeon has not occasionally seen injury result from their use in affections of the urethra, or their use unsuccessful altogether, in skilful hands?

The India-rubber catheter is harmless in the hands of all and in all cases, and can often be used when others will prove unsuccessful.

CHAS. E. SLOCUM, M.D.

DEFIANCE, OHIO, Oct. 5, 1875.

TRICHINOSIS.—A serious outbreak of trichinosis is stated to have taken place in Dresden, where an officer, forty sub-officers and privates, and several civilians are suffering from the disease. The malady also is reported to have broken out in the neighborhood of Lobau.

A FLOATING HOSPITAL FOR CHILDREN.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—At the last session of the Medico-Chirurgical Society of the German physicians, held Sept. 20th, suggestions were made in reference to the summer excursions heretofore arranged by the St. John's Guild, and the question was raised, if it would not be an universal improvement to erect a so-called floating hospital—a steamer furnished in every respect equal to a hospital, and station the same at a suitable spot in the Bay, have boats running from different directions by which sick children could be admitted, and thus give them a chance to have the benefit of pure air for longer periods.

The services of one or several physicians under the supervision of the St. John's Guild would be necessary, and of great advantage to the sick visitors. A committee was appointed to investigate the system now in use of this charitable institution, to suggest improvements and report at the next meeting.

A similar suggestion to the one alluded to appeared in one of the last issues of your valuable paper, and as we don't intend to dispute the origin of the idea thus suggested, but only to express our coincidence in every respect, the Medico-Chirurgical Society instructed their secretary to inform you of the foregoing.

We have ample time throughout the winter to adopt suitable plans, procure aid, assistance and co-operation of the different medical societies, and no doubt the leader of the St. John's Guild will approve of the idea and call the floating hospital in existence as speedily as circumstances will permit.

Very respectfully,

THE MEDICO-CHIRURGICAL SOCIETY.

NEW YORK, October 6th, 1875.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Oct. 10th, 1875, to Oct. 16th, 1875.

WEBSTER W., Surgeon.—Assigned to duty at Plattsburg Barracks, N. Y. S. O. 204, Mil. Division of the Atlantic, October 11, 1875.

BROWN, J. M., Assistant Surgeon.—When relieved by Surgeon Webster, assigned to duty as Post Surgeon, at Fort Wood, N. Y. H. S. O. 204, c. s., Mil. Division of the Atlantic.

NAVY.

October 15.

OBERLY, A. S., Surgeon.—Ordered to the Pensacola Navy Yard.

PARKER, J. B., Passed Assistant Surgeon.—Ordered to special duty at the Bureau of Medicine and Surgery.

RUTH, M. L., Passed Assistant Surgeon.—Detached from the Bureau of Medicine and Surgery, and ordered to the *Minnesota*, at New York.

BEAUMONT, H. N., Surgeon.—Detached from the Pensacola Navy Yard and placed on waiting orders.

The U. S. Steam Frigate *Hartford* has arrived at Hampton Roads, from a three years' cruise as flagship of the Asiatic squadron. The medical officers are: J. H. Babin, Passed Assistant Surgeon; H. P. Harvey, Assistant Surgeon; and R. W. Galt, Assistant Surgeon.

Medical Items and News.

DR. JOHN HUGHES BENNETT, F.R.S.E., late Professor of the Institutes of Medicine at the University of Edinburgh, is announced by the English journals to be recently deceased. He was born on the 31st of August, 1812, and in 1829 was apprenticed to a surgeon in Maidstone. Soon after he went to Edinburgh, where, in 1837, he graduated with the highest honors as M.D. He then studied two years in Paris, and spent some time in German schools. In 1841 he returned to Edinburgh, and soon acquired influential positions, and among others the post of lecturer on histology and the use of the microscope. In 1843 he was appointed pathologist to the Royal Infirmary, and, five years after, on the resignation of Dr. Allen Thompson, he was nominated to the chair of the Institutes of Medicine in the University, a position which he filled most creditably until a recent date. His work on Clinical Medicine is the best known of the numerous and valuable contributions which he made to medical literature—almost his last work being the direction of the Report of the Edinburgh Committee of the British Medical Association on the Antagonism of Drugs. Dr. Bennett was remarkable beyond most of his fellows for unflinching devotion to science, courageous defence of his personal and scientific convictions, unsparing denunciation of what he believed to be error, and resolute furtherance of the objects which he believed to be good for the university, the profession, and the science which he loved so much. He died from the after-effects of lithotomy on a system weakened by constitutional disease, showing to the last the same courage, resignation, and faith which had characterized his life.

DR. EDWARD WARREN.—It is said that Dr. Edward Warren, who went from Baltimore some three years since to serve in the army of the Khedive of Egypt, just as he had arrived at the position of Surgeon General of the Egyptian army, was attacked with ophthalmia of a malignant form. After combating the disease, by all the means possible at Cairo, he was finally compelled to go to Paris, where, after six months of treatment, he has one eye permanently enfeebled, and the oculists declare that if he returns to Egypt the right eye will be compromised and lost. He has accordingly obtained an authorization to practise in France, and is said to be already in a fair way to become a popular practitioner in Paris.

LATERAL DISLOCATION OF FOREARM.—Dr. Andrews, of Bellevue Hospital, finds that the case of complete outward dislocation of the forearm, recently reported by him, is not the first recorded in America, as he supposed. A similar case was reported in THE RECORD of Nov. 1, 1867, by Dr. Theo. R. Varick, of Jersey City.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

Monday, Oct. 25th.—Medical Soc. of the County of N. Y., at the Col. of Phys. and Surg., 23d st., cor. Fourth av.

Wednesday, Oct. 27th.—N. Y. Pathological Soc., at the Col. of Phys. and Surg., 23d st., cor. Fourth avenue.

Thursday, Oct. 28th.—N. Y. Medico-Legal Society, at the Col. of Phys. and Surg., 23d st., cor. Fourth av.

Friday, Oct. 29th.—N. Y. Medical Library and Jour. Assoc., 107 East 28th st. "Report on Therapeutics," by Dr. Mary Putnam-Jacobi.

Original Communications.

REMARKS MADE BEFORE THE NEW YORK COUNTY MEDICAL SOCIETY, OCTOBER 12TH, 1875.

ON A PAPER READ BY DR. W. T. LUSK, "ON THE GENESIS OF AN EPIDEMIC OF PUERPERAL FEVER."

By FORDYCE BARKER, M.D.

MR. PRESIDENT AND GENTLEMEN:—I have listened with great interest to the paper that has been read, which I believe is the first effort of the kind to trace out the origin and development of puerperal fever by an exclusive and systematic study of its genesis, unbiassed by a preconceived theory as to the nature of the disease. It is obvious that study in this direction, if conscientiously and intelligently carried out, must be of great value in clearing up much of the obscurity which surrounds a subject that has been so fruitful in provoking discussion, and has resulted in such a diversity of theory and doctrine.

I am quite certain that all who have heard the paper read must have been struck by the marked ability and faithfulness with which the observations have been made, and the thorough honesty with which they have been reported.

I do not purpose now to offer any general remarks on the disease, but simply to make a few comments on certain points that suggest themselves to my mind by this paper, which is exclusively confined to a detail of such facts as relate to the genesis of puerperal fever in hospitals. While the immense value of hospitals is acknowledged by all, although but imperfectly appreciated by many, their usefulness and importance reach far beyond the inmates who secure the advantage of skilled and experienced physicians and surgeons in relieving suffering, in prolonging and in saving life; for by their educational mission as great schools for clinical study and clinical teaching, they radiate their blessings to every one who suffers from medical or surgical disease, in every part of the country; yet it is a deplorable fact that the hospitals themselves often originate diseases, which to a certain degree detract from their usefulness. That the good which results from them is infinitely beyond the evil, is I think so evident that no argument is needed to prove the assertion.

But in hospitals lacking in proper hygienic conditions, there is generated a poison or miasm, that develops a class of diseases, attended by a change in the fluids of the body, which are called septic diseases.

The septic diseases which peculiarly belong to hospitals, are hospital gangrene, pyæmia, septicæmia, erysipelas and puerperal fever. Their existence in hospitals is a reproach to the profession, just so far as the medical boards have the control and the power of preventing the causes. Some of these septic diseases often occur as an endemic in a hospital, but are never met with as epidemics. Pyæmia and septicæmia are never found as epidemics in private practice or in rural districts; and I have the authority of Professor Eriksen for saying that these are very rare surgical diseases in private practice. I think that these facts have a very important bearing in aiding us in settling the question as to the nature of puerperal fever. Other septic diseases—erysipelas, diphtheria, and puerperal fever—do

occur as epidemics in private practice and in rural districts.

Now it seems to me that there are men who have studied the disease in hospitals alone, who have never had an opportunity to see it as an epidemic in private practice, and who have neglected to study the reports of such epidemics by able and honest observers, who have adopted the fixed opinion that its associations and complications constitute the very essence of the disease. Hence they would abolish the term puerperal fever, and substitute puerperal pyæmia or puerperal septicæmia.

And this suggests another remark; a large proportion of systematic treatises have been written by hospital men, who have studied the diseases of which they treat almost exclusively in hospitals. Hospitals afford an opportunity for complete and careful observation, rarely attainable in private practice, but many diseases are so modified by hospital influence, and especially by nosocomial malaria, that the whole truth is not given in descriptions of diseases which have been exclusively studied in hospitals. I could illustrate the truth of this statement by a reference to several systematic treatises, aside from what has been written on puerperal fever. I will, however, only refer to one, as that has a direct bearing on the subject now under discussion. In Ziemssen's Cyclopædia, now being translated and published in this country, Zuelzer asserts that erysipelas "rarely attains any special frequency and never prevails in epidemic form amongst an entire community;" a surprising statement, for numerous epidemics of the disease described by Zuelzer as erysipelas have appeared in different parts of Europe and in this country.

The septic diseases seem to be divisible into two distinct classes—the one class being specially hospital diseases, not contagious, and never occurring as epidemics. To this class belong hospital gangrene, pyæmia, and septicæmia. The two latter diseases are met with in puerperal women in private practice; but no one ever heard of an epidemic of either surgical or obstetrical pyæmia, and no one claims that either of these diseases is contagious.

The other class of septic diseases are relatively as frequent outside of hospitals as in hospitals; they are contagious, and they often occur as epidemics. In this class I would mention erysipelas, diphtheria, and puerperal fever. I do not assume to mention all the septic diseases, but I now refer only to those which are specially associated with puerperal fever.

Between puerperal fever, and erysipelas and diphtheria, there is a solidarity not found in the relation between pyæmia and septicæmia, or any other disease with puerperal fever. The intimate relation existing between erysipelas and puerperal fever was first pointed out more than a hundred years ago, and has been so strongly confirmed by numerous observations of the highest authorities in medicine, that this fact may now be regarded as conclusively settled. The work on erysipelas and child-bed fever by Dr. Thomas C. Minor, of Cincinnati, recently published, is convincing in its demonstrations of this relation, and Virchow would call puerperal fever *malignant puerperal erysipelas*. They are distinct diseases as regards their morbid anatomy and their clinical phenomena, but they are interchangeable. The poison of erysipelas will develop puerperal fever in a woman recently confined; the poison of puerperal fever will cause in an infant erysipelas, as it will also in an adult whose system is in a favorable condition for receiving the poison. I may be pardoned for giving a striking illustration of these facts, which came under my observation many years ago. In the early months of

1843, a very malignant form of erysipelas prevailed in several towns in Windham County, Conn., and I was told that every woman confined in the infected district died of puerperal fever. My first practical acquaintance with the two diseases began at this time. As I was then a young man living in an adjoining county, having but little to do, I was called upon to do my best, to fill the place of two physicians who had the erysipelas. A few weeks after, a woman was confined in the village of Poquetannoc, New London County, twelve miles from the nearest case of erysipelas or puerperal fever, but she was attended by a nurse who four weeks before had taken care of her brother-in-law, who lived in the epidemic district and died of erysipelas. The woman died on the fifth day after her confinement, of puerperal fever. Two days after her death, her infant died of erysipelas, and exactly one week after, Dr. Gay, who attended the woman in her confinement, died of erysipelas. No other cases of either erysipelas or puerperal fever occurred in this vicinity. I saw the woman and child in consultation, and I attended the doctor during his illness, and it is hardly necessary for me to add that for six weeks after I refused to attend any case of midwifery.

The solidarity between puerperal fever and diphtheria is so marked in some epidemics, as to lead Professor Martin, of Berlin, to regard the diphtheritic process in the genital organs of lying-in women as the only essential element of puerperal fever. I observed and described this diphtheritic process in several cases of puerperal fever which occurred in Bellevue Hospital in the winter of 1860-61. I do not think this was again manifest in the puerperal-fever cases in Bellevue until the winter of 1873-4, when Dr. Lusk, as we have just heard, found it characteristic in many cases. This was also observed in the epidemic of puerperal fever at the same period in the Philadelphia Hospital, and described by Dr. Joseph S. Parry, in his very able paper published in the *American Journal of Medical Sciences*, to which Dr. Lusk also alluded.

Pyæmia and septicæmia bear no such relation to puerperal fever. Either of these affections may occur in puerperal women who have not puerperal fever, or either of them may be associated with or complicate puerperal fever.

For these, and for many other reasons which I have urged elsewhere, I cannot resist the conviction that the study of the genesis of puerperal fever is the study of a distinct essential disease which attacks puerperal women, and only puerperal women.

I have recently read, I think it was in the gossipy memoirs of Raikes, the story of a substantial man in Yorkshire, England, who, some hundred years ago, was appointed justice of the peace. The first case he tried was that of a man against whom he felt a great prejudice, who was accused of poaching. The evidence was strong against the man, but to his great disgust he found the evidence in his defence still stronger, so that he did not dare to convict him. When the trial was over he swore that never again, so long as he lived, would he listen to the evidence on both sides, "for it only confused his mind, and biased his judgment." I cannot but feel that those who regard puerperal fever as only the fever which results from local inflammations, or who consider it as but another name for pyæmia, or septicæmia, non-contagious, and never met with as an epidemic—in short, who deny that it is a distinct disease, must be morally descendants of the famous Yorkshire squire, as they refuse to examine the evidence on all sides, fearing that it will confuse their minds and bias their judgments.

The great practical end in view in the study of the genesis of puerperal fever is, to ascertain what causes of the disease are preventable. A very great advance has been made within a few years in our knowledge of the various agencies which contribute to septic poisoning, and still more striking has been the addition to our resources in the use of antiseptic remedies. Every intelligent obstetrician appreciates, at the present day, as they did not in former periods, the great importance of averting all the predisposing causes of the disease in the patient herself, by an efficient treatment of anæmia and albuminuria in the last periods of pregnancy, a condition which so tends to blood deterioration, and which so favors the absorption of septic poison—by securing to the patient perfect ventilation and good air during labor and the puerperal period, and avoiding the old error of keeping the room too hot, with every crevice closed that will admit air; by preventing delay in labor, in the early resort to the use of the forceps or other resources of our art, when necessary; by effecting the early removal of the placenta by compressing the uterus, thus securing the efficient and permanent contractions of this organ, and thus preventing the retention and decomposition of clots, and the torture and exhaustion of after-pains; by removing immediately after labor all soiled clothes and bedding, and carefully watching that none are ever after permitted to contaminate the patient; by antiseptic washes and injections, to prevent autogenous poisoning; by good nutrition; and lastly, by guarding the patient against the dangers of infection or contagion through the medium of the nurse or the obstetrician. This is a very rapid and by no means complete exposition of the resources we have at command for averting danger from puerperal fever. The success of Winkle, at Dresden, as we have just heard in the paper of Dr. Lusk; the most excellent paper by Dr. William Goodell, "on the means employed at the Preston Retreat for the prevention and treatment of puerperal fever;" the remarkable sixth clinical report of the Rotunda Lying-in Hospital of Dublin, by the master, Dr. George Johnson, ought greatly to encourage the belief that by these and similar prophylactic measures the chances of an invasion of puerperal fever, even in hospitals, may be reduced to a minimum.

But there still remain as great determining causes of this fearful disease, nosocomial malaria and epidemy. How to overcome and to exterminate nosocomial malaria is the great problem which I confidently hope will be solved by the progress of science at no remote period. The devastation which results from this cause, in obstetrical and surgical hospitals, have led some to the extreme folly of questioning the usefulness of hospitals, and others to urge as a radical necessity the extravagantly expensive procedure of pulling down all the old hospitals, and of reconstructing them of such materials that this process can be repeated every few years. But, in the first place, this is not demonstrated to be a radical preventive of the septic diseases which result from nosocomial malaria, for there are well-authenticated reports of puerperal fever in new hospitals for maternity, and of pyæmia and of septicæmia in new surgical hospitals among the first patients received into them. In the second place, I cannot believe that chemical science is so powerless as to fail in finding some means of wholly exterminating this miasm. The experiment has been already successfully tried in this city. I was struck by the remark in the paper of Dr. Lusk, that after the lying-in wards at Bellevue were given up on account of puerperal fever, they were occupied as surgical wards in the service of Dr. James R. Wood, and that

not a single case of septic disease has occurred in them. I am informed by Dr. Dennis, house-surgeon at the present time, that there have been eighteen amputations in patients in these wards, and not a single death. But in some of the surgical wards the fatality from septic disease was really frightful, as reported by the surgeons in attendance; and Prof. Doremus was employed by the Commissioners to disinfect them. I will give his method of procedure, as I wrote it down from his verbal statement to me.

The purification of the surgical wards in Bellevue Hospital was accomplished during the spring and summer of 1875, by the employment of large volumes of chlorine gas.

This powerful disinfectant was resorted to because all the poisonous emanations from the human system are decomposed by it, and thus rendered inert (carbonic acid gas excepted); also because of its diffusive power. Strips of paper were pasted over the crevices around the windows and doors, before generating the chlorine.

Two sheets of lead about eight feet long and four feet wide were turned up at their edges and placed on the floor of the ward to be treated.

In these leaden receptacles several hundred pounds of black oxide of manganese and common salt were placed, to which water was added until the mass, when thoroughly stirred with wooden shovels, had the consistency of a thick mud.

Bowls, basins, and pitchers of sulphuric acid were placed around the leaden vessels in readiness to be applied to the black mixture. To eliminate all the chlorine, the acid should equal the weight of the salt and manganese combined. Water was then poured over the floor to dampen the wood, and the ward was filled with steam until the moisture condensed on the ceiling and walls. The air of the room was so saturated with partly condensed vapor that we had to grope our way towards the vessels containing the sulphuric acid.

The several assistants then held said vessels over the mixture of manganese and salt, and at a signal all poured out the acid at the same time; then hastened to the second leaden trough, applied the acid and rushed out of the door to escape inhaling the chlorine gas which was liberated in immense volumes. Since the amount of poisonous gas was so great that it would have proved fatal to any one entering the apartment, the doors were securely fastened to guard against such an accident.

After the lapse of twenty-four hours, the vessels were again filled with sulphuric acid and placed around the leaden pans. The mixture was then rapidly stirred, and the second application of acid made as in the first instance.

For these two treatments about a carboy of sulphuric acid (160 lbs.) was employed.

After a second twenty-four hours' exposure of the ward to this gas, the windows were thrown open, the residuum of sulphate of manganese and sulphate of soda was removed, with the leaden and other vessels, and the walls and floor scrubbed and dried.

The chlorine was generated by this method, rather than by the addition of hydrochloric acid and manganese, not only because it is cheaper, but because the heat generated by mixing sulphuric acid and water rarefies the gas and facilitates its dissemination through the room and its passage into the porous walls.

Chlorine is comparatively inefficient unless moisture is present, hence steam was employed as described.

After one ward had been thus disinfected and ventilated, the same large leaden vessels were taken to an adjoining ward and the process repeated.

Especial stress is laid on the importance of generating enormous volumes of the chlorine gas, that it may thoroughly permeate the walls. As its odor is very pronounced, persons are liable to err in regard to the quantity, and they merely produce a bad smell and signally fail to destroy the virus with which old or even new walls are at times impregnated.

The water-closets were purified by the use of ozone.

This active form of oxygen was generated by mixing equal weights of manganate of soda and sulphate of magnesia in a dry state, and sprinkling this mixture in and around the basins at night, so that it might remain for a longer period than if applied in the daytime.

When brought in contact with water, *permanganate* of soda is produced, which decomposes in contact with the impurities of the sink, and evolves ozone, by which agent the disgusting and poisonous substances are decomposed, deodorized and rendered harmless.

This treatment was repeated to secure purification.

As this is a cheap method for producing a *permanganate*, the reaction may be of interest.

Three equivalents of manganate of soda, and two of sulphate of magnesia, produce one equivalent of permanganate of soda, one of binoxide of manganese, two of sulphate of soda, and two of magnesia.

One hundred pounds of manganate of soda, and the same weight of sulphate of magnesia, were employed. For generating the chlorine in the different wards over five thousand pounds of the black oxide of manganese, twenty-five sacks of salt, and the equivalent of sulphuric acid were used.

Since this disinfection of the hospital, I am informed by members of the House Staff that there has been but one case of pyæmia or other septic disease in the hospital, and this was a very doubtful one. By the methods adopted by Professor Doremus, or some other method improved by the progress of chemical science, who can doubt that in the future we shall find hospitals as securely freed from nosocomial malaria as we are now protected from small-pox by vaccination.

ANCIENT AND MODERN INUNCTION IN HEALTH AND DISEASE.

By E. C. ANGELL, M.D.

ANointing, or inunction, is one of the primitive processes of human luxury, invigoration, and refreshment. It was employed at so early an epoch that it is by no means easy to trace its origin in remote antiquity. Careful research, however, discovers evidence of this practice among almost all the ancient nations, although it is often impossible to determine the exact nature of the process, the character of the ointment, or even the precise object of its application.

Among the Jews the act of anointing, as recorded in Scripture, was of the simplest character, and consisted usually in pouring oil upon the head from a horn or other receptacle, such as the alabaster box, broken that the precious ointment it contained might be poured upon the head of Christ, as he sat at meat in the house of the Pharisee. This form of anointing was customary as a mark of distinction, as in the case of kings and priests. Isaiah refers to oil as ointment in medical treatment, and anointing was prescribed for the sick by St. James. An oil-bath, according to Josephus, was one of the remedies employed in the case of Herod. The allusion in the Psalms to the ointment

that ran down on Aaron's beard, shows also that oil was used with a profusion doubtless pleasing to the recipient, but which would be far from gratifying to the average American or European of the nineteenth century.

Inunction of the whole body was also practised to some extent in Palestine, in connection with the bath, but among the Greeks and Romans, the two nations which, with the Jews, have impressed themselves most strongly upon the civilization of to-day, the process of what may be called hygienic inunction took a much wider range. The anointing of the Grecian athletes, as a preparation for the exercises of the gymnasium and the national games, was doubtless as thorough a rubbing as could well be administered, and its employment by those who made physical perfection the chief aim of their existence, is ample proof that it was found beneficial, promoting at once suppleness and strength. It was customary to mix sand with the oil thus used, and after the contest the athlete was anointed again, with a view to restoring the tone of the strained muscles. So important was the anointing considered, that special slaves, known as *aliptæ*, were set apart for this purpose.

That the custom of anointing, in connection with the bath, is of great antiquity, appears from Homer, who says in the *Odyssey*:

"Sweet Polyxeste took the pleasing toil
To bathe the prince and pour the fragrant oil:"

and again in the *Iliad* Juno anoints herself with "oil ambrosial sweet;" and Venus anoints the body of Hector with oil scented with roses.

But it was in the Roman baths of Caracalla, of Constantine, of Diocletian and Titus and other emperors, that the art of anointing was carried to its greatest perfection as a means alike of pleasure and of health. It became of such importance, that in all the great *Therma* a special room, known as the *unctuarium* or *electesium*, was provided merely for the keeping of the oils and perfumes. In an ancient painting, showing the apartments of a Roman bath, the *unctuarium* appears like an apothecary's shop, filled with an immense number of vases. So essential did the Roman bathers consider the process of anointing, that they indulged in it twice in each bath, at the beginning, when a comparatively cheap oil was employed, probably without perfume, and again at the close, when costly balsams and fine perfumes were used without stint, being rubbed over the entire body, even to the soles of the feet. The variety of these ointments was very great—cloves, cinnamon, lilies, lavender, myrrh, roses, and many other fragrant substances being used in their manufacture. It was even customary to apply different unguents to different parts of the body during the same bath; oil of wild thyme being rubbed on the head, neck and eyebrows, and oil of watermint on the arms. The rich had precious ointments of their own, which were carried to the baths in small vials of alabaster, crystal or gold. The use of these unguents required the services of many attendants, a point concerning which Spartianus tells an amusing story. The Roman emperor Hadrian, seeing a veteran soldier one day rubbing himself against the marble at the public baths, asked him why he did so. The veteran answered, "I have no slave to rub me;" whereupon the emperor gave him two slaves and sufficient to maintain them. Another day several old men rubbed themselves against the wall in the emperor's presence, hoping for similar good fortune, when the shrewd Hadrian, perceiving their object, directed them to rub one another!

The luxury of the anointing process, as practised

by the Roman bathers, is well set forth in Bulwer's ingenuous romance, "The Last Days of Pompeii," which was written during a residence at Naples, with frequent visits to the baths he describes. Glaucus and Lepidus, two of the personages of the story, after their progress through the bath, meet at last in the *tepidarium*, or warm air-chamber, where, says the author:

"Now the main delight and extravagance of the bath commenced. Their slaves anointed the bathers from the vials of gold, of alabaster or of crystal, studded with profusest gems, and containing the rarest unguents, gathered from all quarters of the world. The number of these smegmata used by the wealthy would fill a modern volume—*Amoracium*, *Megabium*, *Nardum*,—*omne quod exit in um*.—while soft music played in an adjacent chamber, and such as used the bath in moderation, refreshed and restored by the grateful ceremony, conversed with all the zest and freshness of rejuvenated life."

It must not be supposed, however, that the anointing process was by any means confined to those who bathed in a state of health. Galen, in his tenth book, in describing the treatment of a case of marasmus by means of the bath, explicitly directs that the patient be carried into the *tepidarium*, where his whole body must be anointed with oil. Celsus also, in prescribing bathing for those who suffer from affections of the head, not only directs a preliminary anointing, but also says that at the conclusion of the bath the head ought to be rubbed for some time, afterwards dried, and then anointed anew.

Frequent allusion is made to this process in Cameron's "Baths of the Romans," which was published over a hundred years ago, and the late Dr. John Bell, in his able and exhaustive treatise on baths, refers as follows to the anointing process:

"Although we can hardly expect to see a renewal of the practice of inunction, either after the bath or between its stages, to the same extent as in ancient times, yet certainly in many cases it might advantageously be revived, both as a part of medical treatment, and as a means of protection against great and sudden exposures to extremes of temperature."

The opinion of Dr. Bell concerning the advantages of a revival of the process of inunction is remarkably sustained by the experience of Dr. William Taylor, surgeon to the Clerkenwell Infirmary, London. In 1850, Dr. Taylor published a small volume entitled "A New and Successful Treatment of Febrile and Other Diseases, through the Medium of the Cutaneous Surface. Illustrated with Cases." This book appears to be rare, the only copy I have seen having been kindly lent to me by Dr. Otis, and some citations from it, I apprehend, may prove as novel as they are interesting. Additional weight may be given to this work by reason of the marked caution of the author, and his reluctance to lay his method of treatment before the public, until its good effects had been demonstrated by long experience. Their importance may be judged from Dr. Taylor's statement, that during the twelve years, from 1837 to 1849, between 200 and 300 cases of fever occurred at the Clerkenwell Infirmary, without a single death in idiopathic cases; whereas in 1836, before his plan of treatment was adopted, twelve patients died of typhus in one month. As early as 1829, Dr. Taylor observed that fever frequently disappeared in cases where workhouse patients also suffering from scabies were treated for the latter disease with the warm bath and the compound sulphur ointment. An alternative with saline medicine administered in these cases had the credit of curing the fever, but at length recovery took place, in a case

where no medicine had been given, and the inunction fixed his attention and led to a series of experiments in the hot stage of fever, with various simple ointments, from which he concluded that lard was the ingredient chiefly worthy of notice. After still further trial with oil, wax and other substances, he eventually mixed lard and suet in equal proportions, and melted them carefully over a slow fire, and the combination, having acquired about the consistency of common tallow, was found to answer every requisite. This came to be known in Dr. Taylor's practice as "hard ointment," and its application was found highly beneficial in common inflammatory fever, typhus, scarlatina, measles, dropsy, phthisis, insanity, delirium tremens, and hydrocephalus. A multitude of successful cases occurred which it was impossible to record at length in a small volume of 170 pages, but those which are given afford ample illustration of the benefit of a judicious and thorough treatment of the skin in febrile and other morbid conditions. Dr. Taylor did not rely entirely upon the "hard ointment," but also employed other remedies to act upon the internal organs, although in one striking case of typhus, that of Ann Binham, age 23, the patient obstinately refused to take medicine, and yet recovered from a severe attack in twelve days by inunction alone.

With reference to the time and mode of applying the ointment, Dr. Taylor says:

"I have found that it should be rubbed in night and morning, and more frequently in urgent cases, in every part of the skin which is hot and dry. It should be done freely, but gently, during from half an hour to an hour at a time—indeed, until the skin is saturated, when from being harsh, hot and dry, like washed leather, it becomes soft, and yields for the most part, after a few applications, the feeling of velvet. When the skin is in the dry and harsh state of fever it is astonishing how large a quantity of the ointment must be rubbed in before the skin is saturated; but so soon as the latter becomes cool and soft, comfort ensues, and the patient is placed in a vastly improved condition; but dry rubbing does not soften the skin and produce the same free and healthy action.

"When the ointment has been well rubbed in, the countenance indicates its good effect in a surprising manner, and theunctuous friction is superior to the cold or vapor bath, especially in this respect, that with the ointment the object in view is at once attained, the result permanent, and no danger incurred."

Concerning the precise action of fever upon the skin, Dr. Taylor says:

"When fever has set in, the skin, which is naturally highly vascular, and abundantly supplied with nerves, is thrown into a morbid state; it becomes sensitive to change of temperature, and to the touch; it is dry, harsh, and hot; the pores and exhalant vessels become obstructed; the sebaceous glands cease to perform their function; the whole cutaneous surface is parched, dry, and contracted, much resembling chamois leather, and has lost a portion of its vitality. Such a condition of the cuticle is exceedingly obstinate and very difficult to remove, whilst the method of treatment usually adopted is tedious, and requires much time and diligent perseverance. Medicine introduced into the stomach must be continued a long while, and is very slow in restoring the functions of the skin, yet very readily is this state of the skin completely changed by a few applications of the hard ointment, and all symptoms depending on that state are removed at the same time."

The advantages of inunction in febrile conditions Dr. Taylor states as follows:

"Its use extends to all inflammatory, typhoid, and scarlet fevers, measles, and every instance of acute inflammation where there is much heat and dryness of the surface. Fever assuming all the typhoid symptoms will be found to change its character completely under this treatment in twenty-four hours. It especially soothes the nervous system, procures sleep, lessens the frequency of the pulse, allays the heat of the skin and correspondingly the thirst. The pulse may be reduced from 120 to 90 in a few hours after a few applications of the ointment. It corrects the fetid and offensive odor arising from patients; contagion seldom spreads after its use, very rarely even in crowded rooms. When early employed the fever is prevented from running into the continued type, and the patient soon becomes convalescent. Finally, it should be observed that it is always at command, perfectly safe, harmless, and is, perhaps, never contraindicated."

In dropsy of the febrile or inflammatory form, Dr. Taylor found that inunction produced the most favorable results, even in cases treated unavailingly by eminent physicians, and the good effects of this peculiar method were equally striking in cases of hydrocephalus, the improved action of the skin serving effectually to remove the watery accumulations caused by these diseases.

Of inunction in phthisis Dr. Taylor says:

"I have seen great benefit derived from it in incipient cases, as well as in other pulmonary complaints. In acute bronchitis, attended with a hot skin and great expectoration, I have witnessed the greatest benefit, and have known the expectoration to be reduced from a pint in twenty-four hours to three or four ounces in the course of a few days."

In 1830, Esther Cook, age 37, a confirmed lunatic, was admitted to the Clerkenwell Infirmary, and treated for scabies with the usual sulphur ointment. After two or three weeks of rubbing in, her intellect was found to be restored, a fact which led Dr. Taylor to employ the hard ointment in treating cases of mild insanity. The result showed in a surprising manner the sympathy existing between the skin and the brain, and the beneficial effects of inunction upon morbid cerebral conditions, not only in ordinary mania, but also in delirium tremens.

Dr. Taylor's faith in inunction was thoroughly tested in his own case by a severe attack of typhus, which he cured by the free application of the hard ointment to the skin, to the exclusion of other medication, a result which naturally confirmed his confidence in the system.

I have found no striking cases of medical anointing recorded in this country, except in a suggestive paper by Dr. W. R. Fisher, published in THE MEDICAL RECORD of the 27th of March last. A child of four months, almost in *articulo mortis* with cholera infantum, and given up by the family physician, after thorough treatment according to the approved methods, was saved by hourly inunctions from head to foot with warm sweet-oil. "After each application," says Dr. Fisher, "it seemed to be more and more soothed and strengthened. The vomiting ceased; the passages from the bowels improved in color and consistency, and diminished in number." The child recovered entirely, owing its life without doubt to the use of oil by inunction. In another case, a child of the same age, an obstinate intestinal disorder, which had defied internal medication for months, yielded in a week to inunction with sweet-oil applied every night. Dr. Fisher further says:

"In acute inflammation of the lungs, pleura, and bronchial tubes, I have several times seen most excel-

lent effects follow from the use of inunctions. In the lobular pneumonia of children there is no remedy with which I am acquainted that will so speedily induce sleep, relieve distress, and put a stop to the short moaning cry as warm sweet-oil, frequently applied to the whole body. Inunction is likewise of great benefit oftentimes in chronic diseases of the lungs, phthisis, chronic pneumonia, bronchitis, and emphysema."

It is probably in cases of this character, in phthisis especially, and with cod-liver oil as the unguent, that the profession generally is most conversant with inunction, and most thoroughly convinced of its efficacy. Dr. John Hughes Bennett, who introduced this oil into British medical practice as a remedy for pulmonary consumption, is on record in the *Edinburgh Medical Journal* for April, 1853, as declaring that there is every reason to believe that inunction might be very beneficial. In this way, he explained, the fatty matter is introduced into the lymphatics, and serves to elaborate blood through the agency of the mesenteric glands.

Dr. H. W. Fuller, in his valuable work on "Diseases of the Chest," after referring to inunction among the ancients, says:

"It is in constant use in the present day among the natives of Western Africa, who suffer little from the ravages of phthisis. Even in our own country accidental inunction takes place to a limited extent in certain classes of the community. Persons engaged in wool factories, where large quantities of oil are employed, tallow-chandlers, butchers, and others, are necessarily in contact with fatty matter throughout the day, and it has been observed not only that they are usually well nourished, but that they are less liable than others to suffer from consumption. But more than this: experience has established the fact that the endemic method of introducing the oil is often very serviceable in phthisis. Cases have been published by Dr. Simpson, of Edinburgh, and other observers, which are quite sufficient to prove its efficacy, and in my own practice several instances have occurred in which its operation has been signally beneficial. One gentleman whom I saw in consultation gained a stone and a half in weight in less than three months by the persevering use of it, and the physical signs of pulmonary disease subsided greatly at the same time."

I may remark here, in confirmation of the benefits of accidental inunction mentioned by Dr. Fuller, that in a cotton-seed oil-mill at Cos Cob, Conn., now abandoned, coughs and colds were unknown among the workmen in the press-room in constant contact with the oil, but were common enough among the men employed outside. The suppleness of the joints of the press-room men was remarkable, and the full muscular development of those who had worked there long was no less noteworthy. One workman, employed there ten months, is said to have gained twenty-two pounds in that time, while another, in a still shorter period, enlarged the measurement of his chest from thirty-five to thirty-eight inches.

We have now, it will be observed, the testimony of Dr. Bennett in favor of inunction with cod-liver oil in phthisis; the testimony of Dr. Fuller to the same effect, and also to show the anti-phthisical advantages of incidental inunction in the course of certain occupations; the testimony of Dr. Fisher as to the benefits of rubbing with warm sweet-oil in the pulmonary affections of children; and also the testimony, before cited, of Dr. Taylor as to the great utility in lung diseases of inunction with his "hard ointment," composed of equal parts of lard and suet. Here are marked therapeutic results derived in the same class of cases from inunction with one vegetable and two

animal unguents. It may be inferred from this that the beneficial effects arise from the oleaginous quality of the oil or ointment and from the rubbing, rather than from any special therapeutic property such as is generally conceded to belong to cod-liver oil. This inference, if just, is of much importance, for it leaves us at liberty in establishing a scientific system of medical inunction, to choose that unguent which is the most easily preserved pure, which is the most soothing to the skin, most pleasant to the sense of smell, and in a word most agreeable to the person anointed, whether in health or disease.

We come next to the reasons why inunction, notwithstanding its great demonstrated advantages, and notwithstanding its once almost universal use by the conquerors of the world, is now so neglected and so little esteemed by the profession and the public. One of the best modern works on electricity contains this suggestive remark: "There is little doubt that if electricity could be given in the form of pills or powders as successfully as it is now employed, its use would be increased one thousand-fold." There is in my opinion as little doubt that if a dose of inunction could be taken as quickly and as easily as a capsule or a lozenge, "oleagization" would speedily rank with the use of electricity and ether, opium and quinine, as a standard resource in therapeutics.

Such a ready administration of inunction is of course an impossibility. Effective anointing must always and inevitably consume a certain amount of time which will cause hesitation on the part of patients of industrious habits who are not too ill to move about and attend to business. The only way to obviate in any considerable degree this impediment in the way of popularizing hygienic inunction is to make the process so agreeable that it will be found an enjoyment instead of a hardship.

To accomplish this, two things are necessary. These are: *first*, a satisfactory unguent; and *second*, a competent anointer.

A satisfactory unguent must be pleasant or at least inoffensive to the smell: it must not be either gummy or sticky, and it must leave no trace of oil upon the skin after the conclusion of the process. It should also possess properties which will prevent its decomposition by the warmth of the body, that it may not like most unguents become rancid.

The second requisite, a competent anointer, is even more essential and more difficult to secure. Dr. Taylor remarks especially upon the trouble he experienced in finding persons strong enough and patient enough to apply his hard ointment successfully, and when besides strength and patience we require skill enough to make the process a pleasure, we shall not be surprised if we find competent anointers few and far between. Men who are properly trained as rubbers or shampooers in the best bathing establishments are best calculated to supply this want, and to them we may look not in vain for competent anointers. Their labor alone in friction and manipulation often serves an important remedial purpose in rheumatism, paralysis and other diseases, and when to the advantages of dry rubbing the benefits of a proper unguent are added, it is plain that a hygienic combination of no small efficacy is formed. Some attribute the benefits of the anointing mainly to the oil, and others mainly to the rubbing. The truth is both play an important part, and each assists the other. Without rubbing, the unguent would necessarily be imperfectly absorbed, and much of its possible effectiveness would consequently be lost; the pores would be covered, the clothing smeared, and the patient disgusted. Without lubrication thor-

ough searching manipulation is rendered practically impossible from the tendency of dry rubbing to chafe, excoriate and irritate the skin, to an extent often that proves a source of torture.

That the rubbing in of the ointment is a highly beneficial part of the process of inunction, and that its skillful performance is essential to the highest success of that process, I have no doubt; but I am equally certain that in many cases it is the oil directly that accomplishes the greater part of the resulting benefit.

In the wide variety of conditions in which inunction is clearly indicated the aim is generally to effect one or more of the following results:

1. To strengthen weak lungs, as when bronchitis or pneumonia is threatened, or either has been successfully combated, in which event inunction should be followed up daily until the case has been conducted through convalescence to complete restoration. Its value in cases of this character does not admit of question. As early a writer as Pliny says, that olive-oil is good to warm the body and fortify it against cold. The traveller Galton verified this in his own experience, and it was a knowledge of the warming qualities of inunction that enabled Webb to perform the unparalleled feat of swimming the English Channel, the unguent used in his case being the oil of the porpoise. Many a sufferer whose sensitive organization makes him shrink and shiver at the thought of winter long before its approach, might by judicious and persistent inunction escape the expensive and hateful necessity of abandoning home, business and friends every winter for an enforced sojourn in a Southern climate. We can produce examples of this class, who, for the winter and spring months, by frequent recourse to inunction have not only escaped colds, but have found positive pleasure and recuperation in the Arctic weather itself which they had hitherto so much dreaded.

2. To remove debility of whatever form arising from impaired nutrition. Under this head marches the great army of dyspeptics, who will find meat and drink, weight and strength, in inunction. The cases cited from Dr. Fisher's paper illustrate the remedial effects of inunction upon the worst disorders of the digestive system. According to my own observation, improvement in digestion and increase of weight have been the ordinary results of frequent inunction. In one marked case, that of a young man greatly run down by overwork of the brain, twelve pounds was gained in three weeks by inunction on alternate days, after the failure of a three months' trial of other means of recruiting. Within the past fortnight another young man suffering from dyspepsia, severe constipation, piles, some fever and great depression of spirits, has been treated with daily inunction for nine successive days, and has gained in that time seven and one half pounds, has entirely recovered his spirits, and is now practically well in every respect. Ordinary medication tried in his case had not helped him at all.

3. To allay insomnia, hysteria and incipient insanity. Dr. Fisher mentions a diminution of nervous irritation as one of the effects of inunction; and its sedative influence upon excitement, whether febrile or nervous, was very marked in Dr. Taylor's practice. I have often seen patients drowse under the process; and cases have occurred in protracted insomnia, when sleep had proved impossible for several successive days and nights, despite medication, where the process of inunction before completion has left them in a profound sleep, which has usually been uninterrupted until the morning hours were well advanced, when the sufferer has awakened practically to new life.

4. To relieve rheumatism and paralysis. In these

cases the rubbing is probably the major factor of the result, being greatly facilitated, however, by the unguent, which doubtless directly as well as indirectly in some degree enhances the benefits.

5. To abort fevers. The efficacy of inunction in breaking up fever after it was fully established, as recorded by Dr. Taylor, seems to indicate clearly the wisdom of employing it to avert febrile attacks before they are completely developed.

6. To guard against contagion. In the treatment of the plague inunction was found to be not only the best remedy in the cure of the disease, but the best protection against its spread, none of those engaged in anointing having ever been known to contract the malady. In many cases where physicians and others are exposed to infection, or are particularly liable to it, regular inunction during such exposure, or until the susceptibility is overcome, would doubtless be a prophylactic measure of great value.

An objection which is sometimes brought against inunction deserves brief mention. This is the argument that the process must choke the pores, and thus impede the functional activity of the skin—certainly a very undesirable result. Dr. Taylor and others who have practised inunction largely have observed no evidence of such obstruction, but rather a marked improvement in the skin's action; and I am satisfied that perspiration is more facilitated than hindered by thorough rubbing with any smooth, fine, pure unguent. By such rubbing the particles or minute globules of oil are forced through the epidermis, and brought in contact with the lymphatics and blood-vessels of the cutis vera, by which they are taken up and conveyed into the circulation. Without friction the chief part of the unguent would remain upon the skin, a small portion being probably drawn, by endosmosis, through the cuticle. The remainder would cover the surface, and would of course more or less effectually check perspiration in the skin beneath. With thorough rubbing, however, the unguent is forced through the epidermis and carried off, so that nothing is left to clog the sudoriferous ducts. The idea that these ducts absorb the oil and thus become choked, is of course idle, their function being purely excretory; and the notion that the oil is rubbed in through them is equally groundless, as may be seen from the fact that it is much easier to rub oil through the thin epidermis of the back, with its less than five hundred pores to the square inch, than through the thick epidermis of the palm of the hand, with its 2,800 pores to the same area. Further than this, that the action of the skin is not checked, is made doubly sure by the very practical fact, that when one arm or one leg is anointed with thorough rubbing, and the other is left without oil, the anointed limb will perspire in hot air as soon and as freely as the anointed one, and in most cases sooner and more copiously.

During the latter part of 1873, I became acquainted with vaseline, a product of petroleum, which is now pretty well known to the profession and the public. This possessed more of the qualities of a perfect unguent than anything I had before seen, and I sought out the manufacturer and ascertained that he could give me a still further refined product from the same source. This preparation, which I have found the most satisfactory and beneficial in inunction, is white, translucent, odorless and tasteless, and does not, like animal or vegetable oils, become rancid with exposure or age. Being composed largely of carbon, it possesses antiseptic properties in common with charcoal and in a form much more convenient for many purposes. In practice, this unguent is generally perfumed, which does not alter its essential qualities. In its usual state

it is, in consistency, a soft solid, but it may be liquefied by holding the small bottle containing it tightly in the hand for a few minutes. It may be objected to this substance that it is a mineral product, whereas in the cases of successful inunction on record either animal or vegetable oils were used. If, as I believe, the benefits from the unguent arise from its distinctively oleaginous qualities, it is hard to show that a mineral oil may not be equal or even superior to oils of vegetable or animal origin; and it should certainly be no detraction from this substance, that it is furnished by the same kingdom of nature that gives us two such remedies as iron and mercury. I am not, however, so dazzled with the merits of this preparation that I would not gladly employ a better if any should be presented. Indeed the time may come when our unguents will be as numerous as those of the Romans; for I am convinced that "oleaginization"—general inunction for hygienic or therapeutic purposes—has a future before it, and is destined ultimately to develop such value that it will be recognized and employed by every enlightened physician.

Progress of Medical Science.

THE INNER SURFACE OF THE UTERUS AFTER PARTURITION.—The results of the latest researches with regard to the changes which take place in the uterine mucous membrane during gestation and after parturition, are presented in a recent paper by Dr. Leonard Wheeler. The views which he advocates may be stated briefly as follows: The mucous membrane of the unimpregnated womb consists of two layers: superficially, of a layer of cylindrical ciliated epithelium, and deeper, of a layer composed of connective tissue and fibre cells. From the superficial layer numerous follicles dip into or penetrate the connective tissue layer as far as the muscular stratum. In pregnancy the superficial or epithelial layer disappears, and the layer previously underlying it now becomes greatly thickened and more cellular. The cells are exceedingly abundant towards the surface, where they are round in shape, and are surrounded with but little intercellular substance, and have the appearance of epithelium, though doubtless derived from the connective tissue. They cover over and conceal the follicles, which lie imbedded in the tissue beneath. For the purpose of description two layers of the altered mucous membrane may be described: A lower, consisting of glands and spindle-shaped cells; and an upper, nearest the fœtus, consisting of round cells in close proximity to each other. By means of this upper cellular layer of the decidua the union is effected between the maternal and foetal portions of the placenta, and it is through this layer that the line of separation takes place in delivery; consequently the follicles all remain intact within the remaining portion of the mucous membrane of the womb. The cellular layer undergoes rapid degeneration after parturition, is exfoliated, and disappears in the lochial discharge. In this way the buried glands again emerge, and their orifices are exposed. The inner surface of the uterus is soon studded with innumerable little islets of epithelium, from which a rapid proliferation proceeds, and finally, as the uterus continues to contract, it brings the epithelial islets nearer and nearer together, the entire cavity of the uterus is supplied with a new epithelial lining, to which is afterwards added a fringe of cilia.—*Boston Med. and Surg. Jour.*, Aug. 12, 1875.

NITRITE OF AMYL IN SEA-SICKNESS.—Mr. Crochley Clapham, from his personal experience, and in a large class of patients, finds that the nitrite of amyl is the best remedy to be employed (spinal ice-bags might be excepted, but they are not readily accessible), his theory is based upon the belief that undue congestion of the spinal cord is the proximate cause of the malady. He reports the post-mortem examination of a man who was accidentally killed while in the very act of vomiting, and in whom nothing abnormal could be found, with the exception of intense congestion of the spinal cord. The record also adds that the heart was wounded, but only by the fatal blow. This fact recalled to him the similarity of appearances presented by the spinal cord of an epileptic patient who had died in the "status," thus leading him to believe that the nitrite of amyl, which in the hands of Dr. J. Crichton Browne had proved so valuable in the epileptic "status," might be advantageously employed in the treatment of sea-sickness.

Mr. Clapham has used the remedy in 124 cases, with success in 121, in whom there was no return of the vomiting after the administration of the nitrite; the remaining three cases only required a further dose or two of the remedy. His mode of administration is by inhalation, three drops on a handkerchief being held close to the patient's nose. The inhalation should be rapid, so as to obtain the full influence of the drug without a too free admixture of air. Not more than the above dose should be used without medical advice.

The action of the remedy, by relieving the hyperæmia of the spinal cord, may be evidenced by a throbbing sensation in the temples, sometimes rather disagreeable, and by a more or less general flushing and increased warmth of the surface of the body. This warmth is soon followed by a comfortable sleep. Should the sickness recur, which it may do after the lapse of twenty-four hours, the inhalation should be repeated. While under treatment, the patient should be in bed, so as not to interfere with the subsequent sleep; and Mr. Clapham also thinks that it is better to allow one fit of vomiting to take place before using the remedy, not only to insure the *bonâ-fide* character of the seizure, but also because he considers it advantageous, unless the patient be in a very weak state of health.—*The Lancet*, August 21, 1875.

THE PHYSIQUE OF FACTORY CHILDREN.—Mr. Charles Roberts, as a result of extensive investigations on the above subject, arrives at the following conclusions as to the physical condition of these children in England. They are fairly well developed, and remarkably free from constitutional diseases; in general conformation of the body they do not compare favorably with the agricultural population; flat-foot, with a general disposition to knock-knee, is a very common affection among them, while both are rare among the agricultural, among whom there is a general disposition to the opposite state of bow-leg. The development and condition of the teeth in the factory children are very unsatisfactory. Their personal habits contrasted very unfavorably with those of the agricultural districts, and yet, with the exception of flat-foot and the somewhat stunted growth of the children, nearly all of the disadvantages the factory children labor under are to be attributed, in the opinion of Mr. Roberts, to social causes rather than to factory work. He gives tables of weights of various classes of children, showing that the factory children compare favorably in this respect with other children in similar social position, and that they have much improved in weight during the past forty years.—*The Lancet*, August 21, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

GEORGE F. SHRADY, A.M., M.D., Editor

New York, October 30, 1875.

OUR RELATIONS TO PHARMACEUTISTS.

In a previous number we took occasion to remark upon the liability of the degeneration of pharmacy into a mere trade, in consequence of the large business done in patent medicines. The more the subject is viewed from that standpoint the more probable does it seem that the deplorable end is not far off. Even by the majority of those men who would wish to do otherwise, it is asserted that the sale of these nostrums forms a great proportion of their income—so much so that they frankly acknowledge that they cannot afford to dispense with it. They say that they are meeting a popular demand for these articles, and if they do not offer them for sale some others will. This, it is true, is an old argument in favor of evil-doing, but as often as it has been offered it has been impossible to prove that two wrongs make a right. Still, it is the best reason that can be given for acts of which the higher-toned pharmacists are justly ashamed.

In looking around for some remedy for the evil, we invite a conflict between conscience and interest, which, from a strictly business point of view, it has always been most difficult to settle. We sympathize with the apothecaries in their honest endeavors towards reform, and sincerely hope that they may result in something more than discussions and the passage of resolutions in pharmaceutical associations. Not long ago there was a great deal said of physicians who kept drug-stores, and the objection made to the practice was the countenance which these positions gave to quackery. Although they did not openly advise their customers to purchase them, they nevertheless offered them for sale, and in so doing tacitly abetted fraud. The same excuse was offered by drug-store doctors as is now made by the pharmacists, but with no avail. The popular professional sentiment in our larger cities at least was so strongly against the practice, that any physician who wished to be considered orthodox and respectable was forced to sever any business connection

with his accessory establishment. The threat to omit the names of these gentlemen from the *Medical Register* seemed at first unjust, unreasonable, and harsh; but it was, after all, the only way to accomplish a desirable end. This step was a partial acknowledgment by the censors that it was next to impossible to carry on the usual business of a pharmacist, and still be honest to the profession of medicine. As the case now stands, the keeping of a pharmaceutical establishment is under the ban of a reproach, which, from attending circumstances, it is no easy matter to avoid. The store of the apothecary is his only means of support, and it can hardly be expected of him that he should follow the example of the physician who added pharmacy to his means of living as an extra accomplishment. What would be a mere pruning process with one would be a fatal cutting off with the other.

It is true one of the articles of the Code of Ethics, adopted by the College of Pharmacy, calls for the discouragement of the sale of these quack remedies, but practically it has become a dead letter. There does not appear to be anything particularly binding in its provisions. It reads thus:—

“Although not a legitimate part of our business custom, and the necessities of the times warrant us in keeping the proprietary medicines of the day, yet we earnestly recommend pharmacists when called upon for an opinion of their merits to discourage their use.”

We need no better evidence of the attitude of legitimate and high-toned pharmacy on this patent medicine question, than that afforded by the recommendation contained in the foregoing article. The College of Pharmacy of the City of New York is probably the highest tribunal of its kind in the country, and yet, with all its reputation for honesty of purpose, uprightness of action, and zeal for the scientific advancement of the craft, it apparently dares go no farther than simply recommend such as are under the jurisdiction of its influences to do right only under qualifying circumstances.

But has the medical profession nothing to say against the miserable business of nostrum-selling? Are we not, as medical men, encouraging them by refusing to enter our protest against their wrong-doings, by countenancing them as brothers-in-arms, and by recommending them to the patronage of our patients. One can hardly enter any of these shops without being insulted by the glaring pretensions of every quack who cares to offer the pharmacist the necessary percentage for humbugging the people. It is hard to impress our patients with the evils of quackery, when we advise them to go to the very places where it is countenanced by the respectability of scientific pharmacy, and where the sign, “Physicians' prescriptions accurately prepared,” is flanked in on all sides by cure-all pills, wonderful lotions, and infallible pain-killers. We might suggest the propriety of sending our prescriptions to such pharmacists as do not sell these patent medicines, but where can we find them?

THE INDIVIDUAL-TREATMENT SYSTEM.

It might naturally be inferred that this was some newly-devised method of medical treatment, whereas it is merely the modern name given in the Eastern Penitentiary of Philadelphia to the plan of prison discipline, generally known as the separate or solitary system. It only becomes interesting medically when viewed in its effects upon the health of prisoners subjected to its influences. These have been so often discussed, *pro* and *con*, that we need call attention only to one of the most recent contributions to this phase of medical literature, in the shape of a statement by the resident physician of that penitentiary, embodied in the Forty-fifth Annual Report, lately issued. Incidentally, we may state that the report of the inspectors is an inch thick, contains 227 pages of useful and somewhat labor-ed statistics, presents numerous tables twenty inches long when unfolded, and is printed on gorgeous paper worthy of a *livre de luxe*. It is really a work in which, if we were a convict, we should take pleasure in having our vices recorded, even if the people's money must be needlessly squandered to effect such a happy result. Taking the headings of some of the tables of statistics as our guide, we find it to be an abstract of each prisoner's natural relations, his social and educational relations, his moral, industrial and local relations; and there is room enough in the volume for the domestic history of all his other relations. The physician has caught the contagion of inflation, and furnished his proportion of voluminous statistics, sometimes rather injudiciously based on the record of a single solitary individual, as in the columns devoted to numerical data of mental unsoundness, where the latter figures conspicuously as a representative of 100 per cent. in all the items of color, intemperance, conjugal relations, etc., inasmuch as he has no other unsound partner in misery with whom to share the percentage. The special feature of the medical report, however, is an effort to confirm the conclusions of a recent writer on "penology" (the word, we hope, is derived wholly from the Greek and not partially from the Latin, although the writer discusses at some length the subject of masturbation), that in referring cases of insanity of prisoners to any system as the exciting cause a great error has been committed, for it is rarely the result of simple seclusion, and that the individual treatment system cannot be held accountable for the production of pulmonary disease or of disease of any description. Figures are given to corroborate all these conclusions, which might be deemed valuable if based upon a larger number of cases. The prevailing fault of inspectors and physicians alike has been that occasional shortcoming of caterers of other kinds, the attempt to fill out lengthy tables with an insufficiency of articles.

THE ALBANY WATER-WORKS, which take their supply from the Hudson River, are now completed, the capacity of the pumps being estimated at 10,000,000 per diem.

Reviews and Notices of Books.

LESSONS ON PRESCRIPTIONS AND THE ART OF PRESCRIBING. By W. HANDSELL GRIFFITHS, Ph.D., L.R.C.P.E., Licentiate of the Royal College of Surgeons, Edinburgh; Professor of Chemistry in the Ledwith School of Medicine, Paris, etc., etc. London, Macmillan & Co., 1875.

THIS book contains a series of lessons given upon the above subject, and was published in compliance with a special request made by the students who received them. The good sense of the students is shown in the desire to have these most admirable lessons published; and now that they are published, the medical student of to-day, and the practitioner as well, cannot do better than to devote a reasonable share of his time in studying and mastering the principles they inculcate; for, as the author truthfully says, "one of the most crucial tests of an accomplished physician is the diction of a typical prescription."

The study of such a book as this is rendered doubly important by the fact, first, that in general too little attention, at the present time, is paid to instruction in the "art of prescription" in our medical colleges; and, second, that so many fearful mistakes are made in this department by physicians of all classes. The well-known reputation of the author of the book is a sufficient guaranty of profit from its careful study.

THE BETTER WAY: AN APPEAL TO MEN IN BEHALF OF HUMAN CULTURE THROUGH A WISER PARENTAGE. By A. E. NEWTON. New York: Wood & Holbrook, 13 and 15 Laight Street, 1875.

IN this book a strong appeal is made to men with reference to their influence over the character and destiny of offspring. The author firmly expresses the belief that beauty, amiability, timidity, slyness, a disposition to rove, thieve and tattle, craft and treachery, can be transmitted from parent to child with absolute certainty. In the light of this belief he traces the true source of crime to the fathers and mothers of our land, and insists that the predisposition is implanted in the children before they are born. Although the views herein contained have been said to be Utopian and impracticable, the statements of the author have been made with clearness, and his argument embraces much that is practical and of goodly report.

EXTREME ARCTIC COLD.—A French journal recently reproduced a paper read this year by Payer before the Geographical Society of Vienna, "On the Influence of Arctic Cold," a few extracts from which are quite interesting. The author started on March 14, 1874, on a sledge, to make fresh observations on hitherto un-trodden ice-fields. The cold on that day was 42° (Réaumur) below zero. After a time the spirit ration became as thick as oil, and lost its stimulating properties. It was impossible to smoke. Cigars and tobacco were turned into ice. Pieces of metal which the travellers had with them had the same effect when touched as red-hot iron. Great cerebral disturbance took place, accompanied with extreme thirst, difficult to assuage. Every noise was transmitted to a great distance. The senses of taste and smell were almost in abeyance. Mercury could be made into balls. The secretions were augmented, whilst perspiration entirely ceased. Lieutenant Payer is known as an explorer of the highest veracity.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

TYPHOID FEVER—ANTIPYRETIC TREATMENT.

A FEW cases have already been reported, but the case in question presented some features which made it one worthy of study. In the first place, the boy, *æt.* 21, and previously healthy, when admitted with this disease was at once placed upon the antipyretic treatment, by means of quinine. To this was added, after a few days, the hot pack. He was admitted Sept. 2, and on Sept. 17 his temperature was, at 1.30 p.m., $104\frac{1}{2}^{\circ}$ F., when a cold pack was at once ordered. There was no evidence of complication, the aspect of the patient was not particularly marked, and the only symptom which indicated the intensity of the disease was the degree of body heat which could be properly appreciated *only* by the use of the thermometer. This was one point of interest, namely, the inability to judge accurately in all cases of the degree of temperature without the use of a thermometer.

Sept. 17, the cold pack was used at 2.15 p.m., and the temperature fell to $103\frac{1}{2}^{\circ}$ F., but it rose again, later in the afternoon, to 104° F., when the cold pack was again used, and the temperature fell half a degree. The packs were repeated during the night—were continued for fifteen minutes at each application, as a rule—but in the morning of the 18th the temperature was $104\frac{1}{2}^{\circ}$ F., when the pack was used and it fell to $102\frac{1}{2}^{\circ}$ F. It again arose to $103\frac{1}{2}^{\circ}$ F., but the pack again brought it down to 102° F. In the afternoon of the same day the temperature, after a pack, fell to 102° F., then to 100° F., and finally it was brought down to 99° F. This was another rather remarkable feature, namely, the great decline of temperature so short a time before death, for the case terminated fatally on the morning of the 19th, the temperature having rapidly risen to 103° F. before event occurred. Digitalis was at once administered, when the temperature fell to 99° F., but scarcely any effect was produced. The quinine was continued throughout the course of the disease. It was remarked that the fact should be borne in mind that a method of treatment which apparently should succeed does sometimes fail, and that undue enthusiasm respecting any plan of treatment of disease should be received with a certain degree of reserve and scepticism. This patient succumbed, notwithstanding the temperature was brought down to nearly the normal standard.

TYPHOID FEVER—HIGH TEMPERATURE—APPROACHING COMA.

In this case the elevation of temperature was the leading feature, and when admitted the thermometer indicated 106° F., and rising. The patient was admitted in the afternoon, almost comatose, and when the degree of heat was determined he was placed in a cold bath, and kept there almost continuously until midnight, for the rapid rise in temperature after removal necessitated its very frequent repetition. After midnight the baths were repeated every two hours until the temperature was brought down to 102° F. in the afternoon, and 101° F. in the morning, which, it was observed, is *all that should be aimed at* by the application of cold. It was the twenty-fifth day of the

disease at the time of our visit, and the patient was doing remarkably well.

CONVULSIONS—COMA—DEATH.

The brief history of the case presents some points of interest. A female patient, who had had convulsions, was admitted in a conscious state, but soon after admission had other convulsions, lapsed into coma and died. The history obtained was very incomplete, but the general information concerning the case, before admission, pointed towards hysteria. Of course uramic poisoning was suspected, but there was *no* œdema in the case. A quantity of urine, however, was obtained, and when tested was found to have a specific gravity of 1004, but *only a very faint* trace of albumen. Hysterical patients are liable to pass urine of low specific gravity, and here was a bit of a dilemma. But the *character* of the convulsions, those in which there was manifestly *no* *volition* present, associated with this condition of the urine, looked suspicious. Croton oil was administered; a hot-air bath given, which failed to produce perspiration; chloroform during convulsions, which seemed beneficial, and a hypodermic injection of morphine, but the patient did not emerge from the coma.

SLIGHT HEMIPLEGIA—MARKED LOSS OF CONSCIOUSNESS.

The case was interesting in the fact that the seizure of unconsciousness lasted for so long a time, but was accompanied or followed by so slight amount of hemiplegia; and, in addition, it illustrated the difficulty which sometimes arises, in determining with positiveness the pathological explanation of the phenomena presented.

A colored man, *æt.* 33, who was temperate, and never had had syphilis, suffered severely from a general headache of a Friday night. On Saturday morning, while walking upon the street, he suddenly lost consciousness, fell, was picked up and carried to the station-house, and from thence to the hospital, which he reached some time in the afternoon. It was a supposed case of alcoholism, and the patient accordingly was placed in a cell, where, after several hours, he became conscious. The patient was not aware of the fact, when he came to consciousness, that he had a certain amount of paralysis, for to the observer even it was scarcely perceptible in the walk, nor was there anything apparent in his face when the muscles were at rest, but when they were thrown into unusual action it was very evident that the angle of the mouth upon the right side was somewhat lower than upon the opposite side, and in addition, there was a marked diminution of power in the right hand and arm, although not great. There was also marked loss of sensation over the right side of the face, but the orbicularis palpebrarum was affected to only a very trifling extent. There was no aphasia. This man remained in a state of *complete* unconsciousness about sixteen hours, not having the least recollection of anything that transpired after he fell upon the street on Saturday morning. What pathological condition was probably present? There was no cardiac disease, nor had the patient ever had articular rheumatism. He had always been a healthy man. It was believed that there had been a slight extravasation of blood into the brain substance, but the case illustrated well the difficulty of making a positive diagnosis in certain instances.

THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES.
—With the change of the *Medical Times* from a weekly to a bi-weekly the impersonal character of its editorship disappears, and the name of Horatio C. Wood, Jr., is given.

Reports of Societies.

NEW YORK COUNTY MEDICAL SOCIETY.

Adjourned Meeting, October 12th, 1875.

DR. THOMAS ADDIS EMMET, VICE-PRESIDENT, IN THE CHAIR.

ON THE GENESIS OF AN EPIDEMIC OF PUERPERAL FEVER.

THE report made by Prof. W. T. Lusk was based upon an epidemic of this fever which made its appearance in the lying-in ward at Bellevue Hospital in the earlier months of the year 1874, and the object in view was future guidance and warning which might be obtained from a careful tracing, as far as possible, of its origin, progress, and growth. Hospitalism was not regarded as a distinct entity which can at once be recognized and identified, but a knowledge of the workings of the agent must come from an acquaintance with all the elements which may possibly generate its noxious influence. To this end a careful record of the history of every case had been made, noting the development of the slightest symptoms, the condition of the patient mentally and physically, both before and after confinement, the transfer to other wards, the measures adopted to insure cleanliness, etc., etc.

The mental condition was noticeable in a few cases, and, doubtless, had very much to do with the unfavorable termination. Some of these were the mothers who gave birth to illegitimate children, and suffered severe mental depression on that account, while others were thrown into a fearful degree of mental emotion, by the upbraidings of relatives, etc. A certain number of cases terminated fatally, in which the fatal issue was easily traced to well-known causes, such as spontaneous rupture of the uterus, decomposition of placenta and child, rupture of abscess into peritoneal cavity, etc.

Many patients were removed from the puerperal to the medical wards, with the hope that the epidemic might be checked in that way; but from a careful survey of the whole field it was found that this change did no good, and then the confinement ward was closed entirely, and another ward having an excellent reputation was placed at the disposal of the obstetricians. The confinement ward remained closed about two months; was subjected to free ventilation and cleaning, and then reopened, but the sequel proved that the epidemic had not been arrested. During the time that the ward was closed and another occupied, several fatal cases occurred, but the proportions of the epidemic were considerably reduced.

A change of physicians was next made, and the sequel proved that that wrought no particular change in the results obtained in the service, for the occurrence and fatal termination of the disease were as frequent among the patients as before the change was made.

It began to be evident that there was a transmission of the disease from patient to patient, mainly through the agency of nurses; and now the physicians on duty, Drs. Perry and Murray, assumed almost entire charge of the patients, administered the medicines, changed the beds and bedding, and cleansed the genitals of the recently confined women themselves. It was found necessary to do this, for the reason that the nurses would syringe patients having fetid discharges, and perhaps

within two minutes be cleansing the genitals of a newly confined woman, and that without exercising a degree of precaution worthy of the name. These physicians, therefore, assumed these duties themselves to a very great degree. They carefully washed their hands in carbolic water before passing from one patient to another; never used about a patient any article which had been previously used, if it could possibly be avoided; insisted that each patient should have her own syringe and catheter, thereby securing, under the circumstances, the most perfect isolation possible of one patient from another. In this way, be it to their credit, very much was done towards reducing the mortality; but unfortunately the provisions of the hospital were inadequate, and the proper amount of material, such as cloths, napkins, sheets, etc., etc., were not at the disposal of the attendants. These were some of the items to be taken into consideration in making up an estimate of the genesis of the epidemic or the condition of the hospital.

The evidence of direct communication from midwives to patient was so patent, that an increase of nurse force was asked for, but the request was refused by the Commissioners of Charities and Correction. An attempt was then made to obtain aid from other sources, but the demoralization which took place among the nurses already present gave rise to a fearful increase in the epidemic, which exposed most completely a source of transmission that had been in continued existence throughout the course. Two nurses, and only two, were finally added to the force, and the results were marked and beneficial. The obstetrical service, however, was finally broken up, and transferred to Charity Hospital on Blackwell's Island. From the history of the epidemic the professor drew two conclusions.

First—Puerperal diseases may be engendered by atmosphere alone. The nature of the poison is conjectural, but removal of patients to an unaffected locality changes the character of the disease, and the closure of the infected ward for three or four weeks usually restores it to a healthy condition.

Second—In distinction from the above, there is a form of puerperal fever poison with immensely contagious properties, not primarily derived from a miasm, but capable of generating a most fatal disease.

There are two things which may be noted. First, Prof. Lusk, during the entire epidemic, was in the wards two or three hours daily, and yet not a single case in his private practice developed an unfavorable symptom.

Second—Three months later the obstetrical wards of the hospital were occupied by the surgical service, under the charge of Prof. James R. Wood, and in it were treated several cases after capital operations, such as amputations, excisions, etc., and not a single case of pyæmia or septicæmia occurred.

PROF. ISAAC E. TAYLOR regarded the report made by Prof. Lusk as clear and sufficient to place the entire matter, which had caused considerable comment, in its proper position before all.

DR. THOMAS F. COCK regarded it as a horrible outrage that such a report must be made. His acquaintance with Bellevue Hospital extended back as far as 1840, when he was engaged there in a severe epidemic of puerperal fever. At that time the city authorities learned a lesson, at least, which they seemed not to have done at all in the present instance, for a presentment of the case was then made to the grand jury, and they stopped the entrance of all puerperal cases into the hospital, and that stopped the epidemic. The patients who

were already there were transferred to other quarters, and the disease pursued them, and they fell victims to it there. The physicians also, who came to see the cases, transferred the disease to their patients. In 1849 or '50 a similar epidemic broke out and the same facts concerning it were noted. Why were not the commissioners advised in the present instance, and admission of lying-in women to the hospital checked, and not go on admitting them, and leave them to be sacrificed, as they had been? It is said that it was evident that disease was transferred from one patient to another, and yet they continued to admit women for all these months, and thus allow the disease to go on. Why was it so?

PROF. GILLETTE remarked that the record presented by Prof. Lusk was in striking accord with his experience in the Bellevue Hospital twelve years ago. There seems to have been the same causes, the same methods of treatment, the same precautionary measures then as now, nevertheless puerperal fever was an almost constant attendant upon the lying-in service of the hospital. Since that time he had also observed the progress of epidemics of puerperal fever in the same institution. Why they occurred he could only surmise. That the attendants have been hampered, all know too well. With regard to the patients who were transferred to Blackwell's Island, when it was decided to close the obstetrical wards in Bellevue Hospital, he remarked that the commissioners sent him word to make preparations to receive them into Charity Hospital. He objected to placing them in the wards with other women, and insisted that they should be placed in two pavilions upon the ground, one of which had been occupied as a small-pox and fever pavilion, but had been disinfected and properly cleansed. An objection was raised on the ground that such a proceeding would subject the women to the influence of the small-pox and fever poisons. He, however, urged the women into the pavilion, and twenty-three were received direct from Bellevue Hospital. The night of the day they were received one died, and the night of the second day the second patient died. Up to that time nothing had been done in the way of precautionary measures, but at once the clothing was all removed, the hair cropped, and even the hairpins taken away, and the patients were washed in a moderately strong solution of carbolic acid, and this bathing was continued for some days. Quinine was administered freely, and from that time no more puerperal fever manifested itself among these women. Another point was, that during three years previous to the reception of these women they had at Charity Hospital 575 confinements and only eight deaths from puerperal fever. They had come to look upon the disease, so far as its prevention and spread is concerned, as a very tractable one under the rules. For example, when a case is developed the patient is sent away at once, and neither physician nor attendants are allowed to appear in the other wards, nor are the house physicians and surgeons allowed to visit the infected part of the hospital. All are excluded, therefore, except the chief of staff, the visiting and the house physician, who has immediate charge of the patients. In that way they had succeeded almost invariably in arresting the spread of the disease by policing the lying-in wards. There had also been exercised the most scrupulous care with regard to change of bed and bedding, not allowing either to be used by the second patient until thoroughly disinfected, and the same care was also taken with regard to the use of catheters, syringes, etc., etc. The remaining twenty-one women who were transferred had a

higher temperature and pulse than the regular patients in the hospital, showing that the septic germs were there and ready to be developed under favoring circumstances.

DR. MARY PUTNAM-JACOBI regarded the reference which Prof. Lusk had made to depressing moral emotions as the evident cause of the disease in certain cases, when the hygienic condition of the hospital had not been sufficient to develop it, as a point of exceeding interest with regard to the relation between the pathology of this disease and several others. In a goodly number of cases one of the first symptoms manifested under the influence of the puerperal poison is an inability of the uterus to contract properly after labor. This is essentially a nervous phenomenon, and doubtless depends upon paralysis of the nervous centre, which presides over the contractions of that organ. This nervous centre has been demonstrated to be in the medulla, consequently stands in very close relation with the nervous centres, which are affected by depressing moral emotions. When, therefore, the blood has become poisoned by the puerperal miasm, that nervous centre will be in a condition analogous to a nerve centre, first poisoned by morphine and afterwards brought under the influence of chloroform, which, as is well known, permits the anæsthetic to exert its peculiar influence much more rapidly than it would do otherwise. If now a patient has had this nervous centre nearly exhausted by moral emotions, and then is subjected to the processes of parturition, the proper contraction of the uterus is less likely to occur, and in this way an open source for the development of the disease may be furnished. Again, whenever the patients presented the alarming condition spoken of *immediately* after labor, it is evident that they must have been poisoned by something else besides the fluids from the uterus, inasmuch as these do not at that time exist. She was of the opinion that wherever such symptoms occurred before the elapse of twenty-four hours after labor, the same thing must be said, for the discharges become poisonous only after the lapse of about that length of time. We have no source, therefore, in this class of cases, from whence the poison can be derived except the atmosphere, and this is the probable reason why patients who have been admitted to the hospital for several weeks before confinement are much more liable to fall victims to puerperal diseases than when admitted only a short time before confinement.

PROF. FORDYCE BARKER made some remarks, which may be found *in extenso* in the present number of the RECORD.

[Prof. Lusk's paper can be found in full in the *American Journal of Obstetrics*.

THE JOURNAL D'HYGIÈNE, CLIMATOLOGIE, EAUX MINÉRALES, STATIONS HIVERNALES ET MARITIMES, ÉPIDÉMIOLOGIE, is the title of a new semi-monthly published in Paris. It is the Bulletin of the Conseils d'Hygiène et de Salubrité, and is published by Dr. Prosper de Pietra Santa, Inspector of Mineral Waters of the Department of the Seine. The first number appeared on the 1st of October.

BEQUEST TO JEFFERSON COLLEGE.—The late John E. Spencer, M.D., of Morristown, New Jersey, by his will, bequeathed to the Jefferson College the sum of one thousand dollars, to be added to the building of the college; which has been promptly paid to the treasurer by Miss Florence Spencer, executrix. Dr. Spencer was a graduate of Jefferson College, in the class of 1870.

NEW YORK MEDICAL LIBRARY AND
JOURNAL ASSOCIATION.

Stated Meeting, October 1st, 1875.

DR. E. R. PEASLEE, President, in the Chair.

THE paper for the evening, On Inunction in Health and Disease, was read by Dr. A. C. Angell, and can be found in full on page 723.

Discussion followed, which was participated in by Drs. J. C. Peters, Rogers, McLivaine, and the President. There seemed to be something of a diversity of opinion as to whether oils can be made to contribute to nutrition by being rubbed upon the skin. Dr. Rogers was quite certain that very great advantage could be derived from their use in this manner, and especially from the use of cod-liver oil in certain cases.

DR. MCLIVAINÉ, on the contrary, urged that it had been conclusively proved by Bernard that sustaining the system by inunctions or by material thrown into the rectum was a mere assumption; and also that the anointings of olden time were not for the healing of the sick, in the sense that they exerted any remedial influence.

DR. PEASLEE remarked that the question should be considered in the light of maintaining or restoring the normal relation which exists between the sebaceous and the perspiratory glands, for it is well known that the latter cannot perform their function properly unless the former are in their normal condition. Hence, when the skin becomes dry and rough, the sebaceous glands have ceased to be as active as in health, or have ceased to secrete altogether, and the result is that the sweat glands fail to act; therefore, if by means of inunctions the normal elasticity and pliability of the skin can be restored, a very great advantage has been gained, for by this means the escape of effete material from the system, which is constantly going on when the skin is in a healthy condition, is restored. It matters not if the openings of the sebaceous follicles do become closed with the substance employed for inunction, so long as it subserves the same purpose of the normal secretion, or if it stimulates them to the performance of their function. But he could see no reason why life might not be sustained by oils introduced into the system through the skin; and certainly it was a fact well known, that very many patients have been sustained for a long time by nutritious injections into the rectum.

ERGOT *vs.* HIP-BATHS IN TREATMENT OF UTERINE FIBROIDS.—Dr. R. B. Gleason, of Elmira, N. Y., writes: The recent eulogies on the effects of ergot in the treatment of uterine tumors tempt me to offer the profession a point on the subject from my own practice.

Before the days of the use of ergot in such cases, I, of course, had the usual number of cases of menorrhagia dependent on fibroids of the uterus, often non-descended.

A tumor within the uterus is almost the same thing as an intra-mural; a tumor pendent in the vagina is virtually a tumor safely removed. The best means I have found for converting one into the other is cool or cold hip-baths, given daily, with friction over the abdomen. The flow is checked, the back strengthened, and—the great point—uterine contraction is induced and easily regulated, and the tumor expelled.

The digestive impairment of ergot is thus avoided, and the strength of the patient increased instead of impaired. Let ergot be reserved for cases where it has no rival, and where the harm it does is quite outweighed by the good it accomplishes.

Medical Items and News.

TREATMENT OF NÆVUS.—Dr. Emil Steiger, of Prairie du Chien, says:

"I herewith report to you the treatment and cure of a case of nævus, for publication in your MEDICAL RECORD, if you consider it of interest to the profession.

"M. Z., *æt.* 16, came to my office on June 16th, for the treatment of a congenital nævus on her leg. On the outside of the leg was a strawberry tumor, nearly round, of at least one and a half inches diameter, and one-third to one-half inch papillary elevation. Patient complained that for over a year she suffered great pain, that the tumor was increasing, and that the least irritation produced bleeding. Considering the extremely vascular state of the nævus, and the great success I have lately obtained in the treatment of carbuncles from hypodermic injections of carbolic acid, I commenced the following treatment:—I made subcutaneous injections of equal parts of fluid extract ergotæ and acid. carbol.—about fifteen minims to each injection, and one injection from four different points of the periphery, the needle entering about half an inch diagonally towards the centre of the nævus. The surface was painted over with pure carbol. acid, and the whole dressed with simple cerate. At intervals of a week or ten days, four times had I made the injections in the described manner, when harvest-time prevented patient from coming to the city for four weeks. When I saw patient again on August 10th, she told me that a short time ago "the whole thing" (as she expressed herself) fell out. Upon examination I found a small cavity with a healthy, raw surface. I ordered it to be dressed with ungt. plumbi iodidi ζ i., acid. carbol. ζ ss. At present the leg has nearly healed up, leaving only a faint cicatrix, the patient not suffering the least inconvenience from pain, etc., whatever."

TREATMENT OF CHRONIC CYSTITIS.—In the course of some remarks made before the Kings Co. Medical Society, by Dr. J. W. S. Gouley, of New York, on the treatment of chronic cystitis, the doctor said that the disease is usually the consequence of some pre-existing trouble—such as may cause certain alterations of the urinary secretion—such as a foreign body in the bladder, a morbid growth, or an obstruction in the urethra. He had seen cases of chronic cystitis in middle-aged men, which could be traced to no other cause than persistent lithuria; the patients having for months, and even for years before, passed, almost daily, large quantities of crystals or agglomerations of crystals of uric acid, with great frequency of urination, vesical tenesmus, and "burning, cutting" pain along the urethral canal, the urine containing, besides, a variable quantity of pus, and sometimes of blood. This, he said, occurs most frequently among dyspeptics, and such cases of cystitis might properly be called diathetic. When this condition is discovered early, the consequent troubles can generally be averted by properly directed treatment. He recommended alteratives, laxatives, mineral acids as tonics, followed in a few days by mild alkaline waters, and then the Friedrichshalle, or the Hungarian bitter water, proper hygienic management, etc., and related illustrative cases.

In cervical cystitis with inordinate irritability he strongly advocated instillations of nitrate of silver solution, after the plan of Doctor Félix Guyon, of Paris.

The doctor spoke of the cystitis which occurs from excessive use of opium, and advised caution in the administration of this drug to patients already suffering from cystitis.

He also referred to a cervical cystitis, lasting for months, with frequent discharges of slightly purulent urine, often caused by the passage of large sounds in the treatment of urethral strictures. In these cases there is pain after urination, similar to that which occurs in anal fissure after defecation. He asked whether these were not probably instances of pre-existing contracture of the vesical neck, whose mucous membrane has been actually fissured by the distending sound? Should this supposition be correct, would it not be proper to subject the more obstinate cases to the same sort of treatment as are cases of anal fissure? Anal fissure is frequently known to yield very speedily to divulsion of the sphincter, and it is more than probable that fissure of the vesical neck will, in many instances, yield to divulsion of the vesical neck. Divulsion of the urethro-vesical orifice can be made, among other means, by introducing *per urethrum* a soft rubber tube capable of being distended, by water or air, to a given size and at a particular point. He has never resorted to internal incision for contracture of the vesical neck, as advised by the French. In some cases of chronic cystitis, from narrow intractable strictures, he has established free temporary drainage of the bladder, by first making external perineal urethrotomy, and then dilating the neck of the bladder by introducing the index finger. This has usually given excellent results. In only one case of cystitis from stricture has he made free incision of the neck of the bladder, and this patient died.

In far advanced cases of cystitis, where the whole organ is implicated, and where there is concentric hypertrophy with diminished capacity, but where there is no reason to think that the kidneys are hopelessly involved, he advocated cystotomy, such as that recommended by Dr. Parker, of New York; but with the understanding that the cut shall be kept permanently open in order that the bladder may be constantly drained. He thought there could be no objection to this on the score of the inconvenience it might give the patient, since, in most cases that are likely to require the operation, no urine can be retained, and the patient may already be wearing a urinal to keep his garments dry—the bladder having ceased to act as a reservoir for the urine. The doctor stated that he had once succeeded in establishing such permanent drainage of the bladder. The operation was done three years ago, and the patient, who was before very feeble and emaciated, is now well and stout, and the only inconvenience he suffers is getting wet when his urinal is out of order.

He thought that the treatment of chronic cystitis should be in accord with the peculiarities of each case, and with the degree and cause of the disease, and that much judgment and experience are necessary to determine what should be done. While most cases are manageable by irrigations, etc., some are at first greatly damaged by this treatment, and require weeks of preparation by rest, diluents, balsamics, tonics, ice in the rectum, fomentations, hip-baths, rectal suppositories of belladonna and opium, etc. In the majority of instances the treatment should be constitutional as well as topical. The doctor enumerated the various causes of cystitis, and gave a brief outline of the treatment appropriate to each form.

In conclusion, he called attention to the importance of early treatment of the cystitis which so frequently follows injury or disease of the spinal cord, and said

that for the past ten years it has been his practice, in injuries of the back, followed by paraplegia and paralysis of the bladder, not only to draw off the stagnant urine, but from the very first to frequently irrigate the bladder, twice and even thrice daily. This always gives ease and comfort to the patient, and often has much to do with the favorable termination of the case.

EPIDEMIC OF MEASLES AT FIJI.—The *British Medical Journal* gives the following account of the late epidemic of measles in the Fiji Islands, as described by an eye-witness in the *Sydney Morning Herald*:

"The death-rate is not yet made up, but the probability is that 40,000 Fijians died during the four-months' plague. The native population of Fiji is now about one-third only of what it was when I landed here twenty-five years ago. Very few died of the measles, the majority dying of subsequent disease in the form of dysentery, congestion of the lungs, etc. Want of nourishment, or starvation, carried off thousands. All work was suspended for some months. You could pass through whole towns without meeting any one in the streets, which were even completely covered with grass. Entering a house you would find men, women and children, all lying down indiscriminately, some just attacked, some still in agony, and others dying. Some who were strong enough attempted suicide, and not always unsuccessfully. As the scourge became more permanent, four or five were buried together in one grave, and generally without religious service. In some cases the dead were buried in the earthen floors of the houses; in others, just outside the house. The burials were hurried, and the probability is that some were buried alive. In many instances the husband, wife and children all died. In one village all the women died, and in another all the men.

SORE NIPPLES.—The following letter was addressed to Dr. Julius Fehrl, who not long since wrote an article for THE RECORD, on sore nipples:—

DEAR SIR:—I have seen an extract from your article, in the *British Medical Journal*, of September 18, 1875, from the N. Y. MEDICAL RECORD, on "Sore Nipples." I have had a large obstetric practice as an English physician, and have never had a bad case of sore nipples. For many years, when the nipples became slightly sore, I at once applied *zinc shields*; but of late years, instead of allowing the zinc to combine with the lactic acid of the milk, I have applied a preparation of sulphate of zinc and lactic acid (in fact lactate of zinc) and glycerine with starch, between the times of suckling. I think if you try this you will find it unailing, and not only a "prophylactic," but a *specific* in the true sense of the term.

Yours very truly,

ALFRED FLEISCHMANN,

Late Asst. Phys. Accoucheur, King's Coll., London.

A NEW PROCESS FOR STAINING TISSUE.—Another process, introduced by the well-known histologist, M. Cornil, consists in the employment of "violet methyamine." Its merit is said to be that its constituents separate into red and blue elements, which have different affinities for the tissues acted upon, and therefore fits it especially well for organs in a state of lardaceous degeneration, the lardaceous part taking a red tint, the normal a blue. M. Cornil has by this process determined that the lardaceous change takes place first in the interior of the small arteries. One objection to the method will prevent its being of very great practical value, that is, the disappearance of the coloration in specimens mounted in Canada balsam, glycerine, etc.

A JUNK SHOP IN A HORSE'S INTESTINE.—At a post-mortem examination made of a horse which had died from an obstruction in the bowels, the following articles were discovered in the colon: Eleven hundred nails, ranging from about half to an inch and a half in length, a quantity of small screws, buttons, curtain hooks and other miscellaneous items of a hardly less digestible material. These foreign ingredients were smooth and thin by the friction to which they had been subjected, a proof of the long time they had been in the beast's intestines.

REMARKABLE PERSISTENCE OF CARDIAC ACTION AFTER DEATH.—A remarkable case is reported by R. Stewart, M.D., in the *Medical Times and Gazette* of Sept. 25th ult. On July 4th, 1872, Dr. Stewart attended a gentleman about seventy-two years old, who complained of fatigue, heat, and pain in his head. After prescribing for these symptoms the doctor left, but was sent for again at eight o'clock, and found his patient apparently dead. The jaw had fallen, the eyes were fixed, the body was cool, and the head hot, but, on applying the ear to the chest, the heart was distinctly heard beating twenty-seven times a minute. Artificial respiration was practiced, and air and ammonia blown into the lungs. Under this treatment the heart-beats became more frequent and forcible, but no respiratory effort could be produced.

At ten o'clock the heart was still beating, and the attempt to re-establish respiration so stimulated the heart that a radial pulse became perceptible. The body gradually became cold and rigid, and the cardiac pulsations more feeble. Between five and six o'clock of July 5th the throbbing of the heart was very feeble and slow, and could not be accelerated, and a little after eight o'clock there were signs of decomposition by appearance, odor, and lessening rigidity. The patient was evidently dead then; but, as Dr. Stewart well asks, what was he before?

A COLONY OF LUNATICS.—At Gheel, a village in Belgium, there is a colony of lunatics under the care of Dr. Bulckens, and during the recent Medical Congress at Brussels it was visited by about forty members, who were greatly interested in what they saw and heard of the condition of these unfortunate people. The lunatics, who number about thirteen hundred of both sexes, are not kept in an asylum, but board and lodge with the inhabitants. The patients come from all countries, and belong to all ranks of society, being accommodated according to their means. The more dangerous lunatics are placed in outlying isolated houses. The inhabitants are all more or less engaged in the surveillance of those who are quartered upon them. There is a dépôt, asylum, and hospital, to which cases of violence and dangerous illness are sent. It has been suggested that the system would work well elsewhere, and it would be interesting to learn whether this constant association with the demented tends to induce any form of mental deterioration among the villagers of Gheel.

DISEASE AMONG PIGS IN IRELAND.—The *Veterinarian*, commenting on the fatal malady which has broken out among the pigs in the south of Ireland, especially the district around Watertford, inclines to the opinion that the pigs are suffering from typhoid or enteric fever. This disease is by no means uncommon in Ireland, and when once it has gained a footing in a district, is sure to spread and assume a fatal character for want of all sanitary regulations on the part of the owners of the animals. Typhoid fever in pigs, which has long been known to be contagious, is now also proved to be infectious in the ordinary acceptance of the term.

MEDICAL SOCIETY OF COUNTY OF NEW YORK—ANNUAL ELECTION.—At the Annual Meeting of the Medical Society of the County of New York, held October 25th, 1875, it was ordered that certificates of membership be granted to the following gentlemen: Drs. E. M. Stein, W. B. Hull, C. J. Dumond, T. H. Burchard and W. M. Carpenter.

Upon motion made by Dr. Gurdon Buck, and seconded by Dr. Austin Flint, Sr., a committee consisting of three members was provided for, which, together with the President of the Society, shall confer with delegates from Philadelphia in reference to matters pertaining to the forthcoming Medical Congress to be held in that city in 1876.

Upon motion of Dr. E. Eliot, the Comitia Minora was empowered to select such committee.

The annual election of officers resulted as follows:

For *President*, Dr. H. B. Sands.

For *Vice-President*, Dr. Thomas Addis Emmet.

For *Recording Secretary*, Dr. Alfred E. M. Purdy.

For *Corresponding Secretary*, Dr. F. A. Castle.

For *Treasurer*, Dr. H. P. Farnham.

For *Censors*, Drs. H. T. Hanks, T. T. Sabine, J. E. Janvrin, E. J. Janeway, C. W. Packard.

For *Delegate* to State Medical Society, Dr. T. E. Satterthwaite.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Oct. 23d, 1875, to Oct. 30th, 1875.

EDWARDS, L. A., Surgeon.—Relieved from duty in the Military Division of the Atlantic, to proceed to Philadelphia, Pa. and, upon arrival, report by letter to the Surgeon-General. S. O. 208, A. G. O., October 15, 1875.

JANEWAY, J. H., Assistant-Surgeon.—Assigned to duty at St. Augustine, Fla. S. O. 153, Department of the South, October 15, 1875.

HEIZMANN, C. L., Assistant-Surgeon.—Extension of leave of absence further extended fifteen days. S. O. 213, A. G. O., October 21, 1875.

HOFF, J. V. R., Assistant-Surgeon.—When relieved by Assistant-Surgeon Jaquett, assigned to duty at Fort McPherson, Nebraska. S. O. 113, Department of the Platte, October 18, 1875.

NAVY.

October 20.

KIDDER, JEROME H., Passed Assistant Surgeon.—Ordered to special duty connected with the Transit of Venus Commission.

October 21.

HUGG, JOSEPH, Surgeon.—Detached from the *Canandaigua*, and placed on waiting orders.

CORNDON, C. G., Assistant Surgeon.—Detached from the *Canandaigua*, and placed on waiting orders.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

Monday, Nov. 1.—N. Y. Neurological Soc.

Thursday, Nov. 4.—N. Y. Academy of Medicine, 12 West 31st st.

Friday, Nov. 5.—N. Y. Medical Library and Journal Assoc., 107 E. 28th st.

Saturday, Nov. 6.—N. Y. Physician's Mutual Aid Assoc. Annual Meeting and Election.

Original Lecture.

ON THE TREATMENT OF TYPHOID FEVER.

By W. H. THOMSON, M.D.,

PROF. OF MATERIA MEDICA IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

LECTURE III.

COMPLICATIONS.

GENTLEMEN:—We will conclude now with the treatment of the complications and accidents which may arise in the course of a typhoid fever, and which may either cut short the case by death, or else prolong the illness to an indefinite period beyond the normal limits of the complaint. The first and commonest of these is a WEAKENING OF THE HEART, due mainly to fatty degeneration of its walls induced by, and ordinarily proportioned in its extent to, the degree of the pyrexia. So debilitated may the heart become, that your patient may die suddenly from syncope upon rising too quickly in bed, or on his feet, though then fairly convalescent from the fever. But it is generally from visceral disorders, induced in the later periods of the fever by this state of the heart, that a watchful attention on your part for the symptoms of cardiac feebleness becomes so necessary, because even in the worst cases timely measures may avert its chief perils. The danger from this source is to be apprehended most in those patients who had weak or damaged hearts before they contracted the fever. Thus the prognosis of typhoid is much more grave in corpulent, short-winded people than in the lean and muscular, and in those whose long-continued or free use of alcohol has produced the fatty heart of drinkers. I saw also, lately, a young lady, who had been suffering for some years from valvular disease, succumb rapidly to dilatation of her hypertrophied heart occurring during a comparatively slight attack of pericarditis, following upon a typhoid fever from which she had apparently so far recovered as to be able to take a long railroad ride, but which very probably was the immediate cause of fatally aggravating her cardiac lesions at a time when the fever had specially disposed the ventricular walls to dilatation. The indications of cardiac weakness are to be watched for, first, by a careful attention to the action of the heart itself; and secondly, to the state of the pulse. The character of the heart-beat is of greater value than the state of the pulse, for the latter varies to a remarkable degree in typhoid, so as to be very puzzling sometimes to inexperienced observers; but you can scarcely fail to obtain trustworthy signs of impending danger if you practise auscultation faithfully. In the first stages of the fever, and in many cases throughout its course, till the beginning of the defervescence, the frequency of the pulse is strangely disproportioned to the height of the thermometric range. I have repeatedly known it to fall short of 90 for days together, while the thermometer stood at 104° or higher, and during the first week the diagnosis of this fever has often been missed because the pulse remained slow and regular. During convalescence, however, you may have the frequency suddenly increase by twenty or even thirty beats, from changes of position, slight errors of diet, etc., while the thermometer may be even below its norm. A *persistently* rapid

pulse, nevertheless, is not a favorable symptom, for it indicates a state of cardiac weakness, which is the more to be apprehended if the pulse be weak and compressible as well, and worse than all, if it be dicrotic. On the other hand, cardiac weakness is certainly diagnosed whenever the apex beat diminishes in force, and the first sound of the heart grows faint or muffled. In some these signs are present before acceleration of the pulse is developed, but whenever noted you should not delay your recourse to cardiac stimulants. It was upon this indication that Graves based his excellent rule for the administration of alcohol in fevers, and it is desirable to emphasize this truth, so as to prevent the abuse of stimulants, which prevailed so extensively of late, chiefly from the extreme advocacy of alcohol by the late Dr. Todd, of London. It should be borne in mind that alcohol stimulates best when first administered, and progressively loses its power the longer, as well as the more, it is taken. If we begin with free doses in the first week, we certainly do *not* forestall by it the prostration of the third week, but instead, reap the evil of not securing the benefit we would have from it if it had been withheld until actually needed. If we dreaded, for example, the loss of blood from a proposed surgical operation, still we would scarcely think of beginning the stimulation of the patient a week before he was to be operated upon, and yet some such idea must have influenced those authors who spoke in favor of early stimulation in fevers. When cardiac feebleness, however, begins, we should commence with our alcoholic doses, and aim to make them tell upon this one condition, and on no other. I have small faith in either the pyretic or the nutritive value of alcohol in fever, not that I deny these properties to this agent, but because they are of such minor importance in comparison with its undoubted efficacy in stimulating the heart, that our administration of it should be regulated by the best means of obtaining the latter result alone. Hence I do not recommend the employment of wine in any form, but rather the administration of strong spirits like brandy or whiskey. There is no doubt, too, that the spirit should be given only with food—in this case milk—if we wish to prolong its sustaining effect; not necessarily in the milk, but if so preferred by the patient, in water, just after the milk is taken. The dose also should be one which will surely increase the power of the cardiac systole, which of course will vary either with different individuals, or at different times with the same individual; but what is meant by this recommendation is, that a few free doses are better, as a rule, than a great many small ones. Besides alcohol we have a very potent cardiac stimulant in sulphuric ether, and which, moreover, is such a near relative to alcohol that in this condition it is best administered in alliance with it, so to speak. An ounce of brandy at one time, and then at the next dose half an ounce, with a drachm of Hoffman's anodyne, is far more likely to sustain an enfeebled heart than three ounces of brandy divided up into six doses. Ammonia is another cardiac stimulant, but I would advise your reserving it for the next complication we are going to speak of. Occasionally in the course of this fever, as well as in typhus, scarlatina, or measles, a dangerous collapse may unexpectedly occur from a sudden PARALYSIS OF THE HEART. This organ begins to beat very feebly, and seems able to propel the blood only into the neighboring large viscera, so that the lungs become greatly congested and severe dyspnoea develops, indicated by rapid and very shallow breathing. The liver and kidneys also become engorged, while the whole surface turns cold, white, and shrunken, and the muscles of the

extremities, as in the calves of the legs and flexors of the forearm, become cramped from the arterial blood not reaching them. The patients also complain of a dreadful sense of vacancy or sinking, referred to the pit of the stomach; and though the skin is very cold, yet they feel as if they were burning inwardly, and beg for ice or cold drinks on account of the intense congestion of the stomach and other parts connected with the portal circulation. Meantime the anæmia of the surface causes the eruption to fade to such a degree as to fill the nurses or friends with the alarming notion that the scarlatina or measles has "struck in." These emergencies require prompt treatment, for your patient may either die in them outright or succumb afterwards to some visceral derangement, such as pneumonia, or, more commonly, renal suppression. The heart being the seat of the trouble, the first thing to do is to apply saucers or small plates dipped in hot water to the epigastrium. Dr. Wood, Sr., of Philadelphia, mentions applying a live coal to the pit of the stomach in a case of typhus, and after recovery the patient described its sensation as positively agreeable from the relief he experienced from the distressing feeling of vacancy there. The next thing to do is to give one or more hypodermic injections in this neighborhood of about forty minims of pure brandy. This is an exceedingly valuable measure in all conditions of cardiac collapse, and I have never seen any local irritation produced by it. The patient's friends will not wait for a lvice as to dry heat to the extremities, as well as sinapisms, friction, etc., and they are all useful; but if reaction is protracted you should first wrap the patient in a sheet, upon which a boiling infusion of a drachm of capsicum to the quart of water has been poured, and then over this a blanket; and lastly, if everything else fails, a hot bath not above 103°, continuing meantime hypodermics of brandy rather than by the mouth, nothing but pieces of ice being permitted to be swallowed. It is singular to note sometimes how temporary these cardiac prostrations are, for your patient, on coming out of them, may subsequently run quite a favorable course with his malady; but this remark applies much more to the eruptive fevers proper than to typhoid, where they are more prone to recur, owing to the longer continuance of the pyrexia.

PNEUMONIA in typhoid fever is not an uncommon complication. The first signs of its approach are a rise of temperature and increased frequency of the respirations, rarely cough or rusty sputa. The pneumonia, indeed, is generally preceded for some time by hypostatic congestion of the lungs, and this is a direct consequent upon weakness of the right side of the heart, and hence is the more to be expected in patients who have been troubled previously with chronic bronchitis or emphysema. The pneumonia, in the great majority of cases, is lobular, and not of the croupous lobar form, complicated by pulmonary œdema, and very rarely accompanied by much pain. It is now that you should have recourse to ammonia, and I recommend the carbonate in doses of ten grains every two hours, with the Hoffman's anodyne one drachm, and ten minims of tincture of camphor. The belladonna tincture in doses of ten to fifteen drops every three hours is a valuable cardiac stimulant in this condition. The cold bath should by no means be omitted, for it often clears the lung up remarkably of its congestion, from the relief it affords to the enfeebled heart. It is well also to stimulate the surface of the chest frequently by a liniment of ol. terebinth., aq. ammoniæ, ʒi, lin. saponis ʒij. Owing to the pulmonary derangement which typhoid fever induces, it is always a risk to those who are inclined, either hereditarily or otherwise,

to phthisis. It is therefore important in them to be rid early of all signs of congestion of the lungs, and hence you should persistently employ surface irritants to the chest with them as long as any evidence of respiratory feebleness remains during convalescence. Owing to the laws of nervo-vascular connection, which I have had frequent occasion to allude to in my lectures, between the cutaneous and the vaso-motor nerves of the arteries of deep-seated organs, we should not neglect stimulating the thoracic surface by every means in our power, and for this purpose I know of no measure so effective as free faradization, either for causing absorption of pericardial or pleuritic effusions, or for the removal of a pulmonary exudation. The electrodes should be armed with moistened sponges, and held about six inches apart, and moved slowly over the chest anteriorly and posteriorly until the surface becomes well reddened, which it usually does in fifteen minutes, with a current of not too rapid intermissions.

We have already alluded to the treatment, or rather to the prevention, of the commonest complication connected with the alimentary canal, namely, the DIARRHŒA. If the pepsin and bismuth do not, however, check a too great flux, I would recommend a prescription of mine, which I have long relied upon for the treatment of chronic diarrhœa, from whatever cause, viz.: terebinthine resin. ʒij., argenti nitrat. grs. v., pulv. opii grs. v. M. Ft. pilul. lx. The one objection to these pills is the number of them that have to be taken, namely, three at a time three times a day; but I have scarcely ever failed to check a flux by them, no matter how long its former continuance. Dr. Wood speaks very highly of turpentine as calculated to promote the healing of the intestinal ulcerations, both in this complaint and in the diarrhœa of phthisis, and it is possible that the silver may be an adjuvant in that action. When the patient cannot take the pills, I substitute a third of a drachm of the oil of turpentine in mucilage, with ten minims of laudanum to each dose. During convalescence, your patient's temperature and pulse may rise, and all progress for the time be arrested by the formation of scybalous masses in the large intestine, which may even alarm you by occasioning small, loose movements, streaked with blood. There is not much danger of intestinal hemorrhage, however, from them; but the bowels should be at once relieved by large enemata of linseed oil, molasses, and warm water, helped by a pill of ext. belladonna, gr. ¼, with five grains of soap. I know of nothing better than the above-mentioned pill of turpentine and silver for the INTESTINAL HEMORRHAGE of typhoid, a complication, indeed, not nearly so likely to occur when pepsin and bismuth have been used as recommended, as when the intestinal contents have been allowed to remain for a long time in a fermented condition. Should tenderness on pressure at the cæcum, however, persist for a length of time, do not let the fear of debilitating your patient prevent you from applying two or three leeches over the affected part. This will do more towards preventing the worst danger you can fear in this region than anything else that I know of, and I never saw any one the worse for the insignificant loss of blood which it occasions. Of course, should symptoms of INTESTINAL PERFORATION surprise you, the course to be pursued then cannot be doubtful. Opium should be given in any dose that will produce seminarescism, and not until the patient shows the signs of the action of this, our main-stay in peritonitis, should you cease to ply him with it. You are occasionally annoyed also with a trouble at the entrance of the ali-

mentary canal, namely, with PAROTITIS, accompanied frequently with otitis. For the first, I would recommend the application of ungu. stramonii ℥ ss., chloral hydrat. ℥ i., pulv. camphoræ ℥ ss., ol. gaultheriæ gtts. xii., several times a day, and poultices; for the otitis, a persevering douche of the ear with warm water, best applied from those convenient contrivances, Potter's hydrostatic bags.

MEINGITIS, fortunately, is a comparatively infrequent result of typhoid, for when it occurs it is of bad augury. It is generally preceded by wakefulness, with fits of screaming, or else a delirium which seems out of proportion with the amount of fever. The diagnosis becomes quite certain when there is rolling of the head and retraction; the pupils are also commonly very sluggish. The patients are very fond of cold affusions to the back of the head, even if they refuse to have an ice-bag applied. The most efficacious measures against this complication I would enumerate in the following order: First, blisters to the nape of the neck and occipital region; secondly, ergot; and lastly, iodide of potassium. The action of a large blister in some cases is followed by the most striking improvement in the cerebral symptoms ever witnessed. I once saw a patient who had been first comatose and then imbecile for six weeks, after an attack of ordinary cerebro spinal meningitis, so that she passed all her motions in bed, return permanently to complete consciousness as soon as the blister began to act. Ergot, to be of any use in this condition, should be administered in drachm doses of Squibb's fluid extract three times a day. I am not certain how much efficacy can be ascribed to the iodide, but if it does good the doses must not be less than a drachm a day. If there be much headache, the addition of Squibb's fluid ext. conium often relieves this greatly, and I am sure that this drug greatly promotes the action of the iodide in syphilitic cases. If the meningitis assumes an active form with increase of temperature and mania, the application of two or three leeches to the mastoid process relieves the patient, as evidently in this case as it always does in ordinary intercranial inflammations. There is one point, however, on which much stress ought to be laid, and that is, to prevent at any price WAKEFULNESS during the decline of the fever and during the convalescence. We include under this term also sleep troubled by dreams. The weakened brain must have rest, or it may be very long before it will recover its former state, and for this indication I will conclude by recommending the following prescription: R. Magendie's sol. ℥ i., acid. hydrocyanici, dil. gtts. xii., chloral hyd. ℥ ij., elix. simplicis ℥ i., aq. camphoræ ad ℥ iij. Dose: two or three teaspoonfuls at night.

who have distinguished themselves as ovariologists. In regard to myself, living as I do in a country village, my experience is of course limited, yet it adds a mite to the general fund of experience on the subject. The two points to which I would call the attention of the profession, and especially new beginners, is, first, the position of the patient; and second, treatment of the pedicle. It is all-important that none of the cystic fluid should enter the abdominal cavity, and the position of the patient should be such as to avoid this accident; therefore, after making the external incision I place the patient on the edge of the table, and turn her over almost on her face, two good assistants holding her in this position. I then puncture the sac, and draw off the fluid, puncturing the sacs as they present themselves at the external opening, which they readily do by a little traction on the emptied main sac (the force of gravity aiding very materially in this respect), until each and every sac is evacuated, and drawn through the external incision (which is easily done if there are no adhesions), until you come to the pedicle, the securing of which is a proceeding of grave importance. As the different plans of treating the pedicle are familiar, I need only to say that I prefer the silk ligature, left hanging out at the bottom of the external incision. I have just discharged my seventh patient, in six of which I used this method; five recovered, and one case was so adherent that it could not be removed. To the clamp I have decided objections. In the first place the pedicle is often so short as to preclude its use; but if this objection does not, if the bowels become tympanitic from any cause, a painful tension is produced upon the pedicle, or if the patient vomits or coughs, a violent jerking upon the pedicle is the result, which is not only productive of pain, but may be attended with serious results, from the clamp tearing out, or its inducing inflammation. No such results can ensue with the ligature. Then again, in one instance which came to my knowledge, where one of our most eminent ovariologists operated, the pedicle brought out and secured by the clamp prevented the healing of the external wound, and after weeks of suffering she died, apparently of no other cause. In my last operation, which was performed on the 16th of last month, I removed a multilocular tumor, weighing between sixty and seventy pounds. I tied the pedicle in three parts. In ten days the ligatures came away, and in just four weeks I called on my patient and found her in the kitchen, wiping up the dinner dishes. Her convalescence was unattended with a single unpleasant symptom. In my opinion the ligature will come to be the method of all others for securing the pedicle. The pedicle should be tied in two or three parts, the ligature not large, and drawn very tight, and in a few days it will separate, and the wound heal.

October 15, 1875.

Original Communications.

SOME POINTS IN OVARIOTOMY.

By E. P. BENNETT, M.D.,

DANBURY, CT.

So much having been written on the subject of ovariotomy, and the operation having become so fully established as one of the legitimate operations of surgery, that at first thought it would appear as if the subject was almost or quite exhausted: still there are two points upon which there appears to be a difference amongst those

AMERICAN GRADUATES IN GREAT BRITAIN.—A correspondent of *The British Medical Journal* states that out of two hundred and twenty-eight graduates of foreign schools practising in Great Britain, those who hold diplomas from the United States are as follows: New York, sixteen; Pennsylvania, ten; Massachusetts, one; Illinois, one; and Ohio, one.

ACCORDING to the *Academy*, there exists in St. Mark's Library, at Venice, a MS. in the handwriting of John Locke, consisting of notes on medical subjects, which, our contemporary observes, is the more curious if, as has been said, Locke was averse to allowing it to be known that he once intended to practise medicine.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

CHOREA.

Two cases of this disease were seen which presented some points of interest. One patient, a girl *æt.* 17, was suffering from her second attack; the first attack occurred when she was 11 years of age, was probably developed by overwork, and lasted for one month. Her father died of heart-disease, but her mother is still living and healthy. The treatment since admission had consisted in the use of a general tonic course, and to this arsenic had been added, but without causing any improvement. Strychnia was substituted, beginning with $\frac{1}{20}$ th of a grain once a day, and was daily increased until a trifling amount of muscular rigidity was developed in some part of the body. Her improvement was manifest at once and the case went on to recovery.

The second case was a girl *æt.* 10 years, who had had an attack when she was 5 years of age, and the attacks have been repeated *yearly*, but have not as a rule lasted very long. Father healthy, and mother died of consumption. Her treatment was to consist of a generous diet and the use of strychnia. The choreic movements were very marked, and ether spray to the spine was to be added. There was *no history of rheumatism* in either case. In the latter, the disease was probably due to fright. At the end of three weeks the girl had nearly recovered.

A POINT IN DIAGNOSIS.

Special attention was drawn to the fact that this patient, who was suffering from an attack of ague, had a slight herpetic eruption over the nose and upon the upper lip. It was regarded as in the main correct in distinguishing remittent, intermittent, cerebro-spinal, and some other diseases from typhus and typhoid fevers, for in the latter such an eruption is only *very rarely* present.

ACUTE ARTICULAR RHEUMATISM—PLEURISY—PERICARDITIS.

It was a nice point in diagnosis in this case to determine whether the friction-sound which was present was pericardial or pleuritic. The history of the case was as follows: a male patient *æt.* 30, whose previous health had always been good, "sat upon a cold stone" three weeks ago; did not have a chill, but a few hours after was seized with a pain in the left hip-joint, which soon travelled to almost every joint in the body, and was accompanied by tenderness upon pressure, heat, and more or less of swelling. He had also suffered considerably from pain in the left side, just under the nipple, which was increased by a full inspiration, and obliged him to lie upon his back; but there was no cough or expectoration. Physical examination revealed a friction-sound over the præcordial space, which was synchronous with the heart-beat. Was this sound evidence of pericarditis, or was it pleuritic? The fact that it was synchronous with the heart-beat seemed to exclude pleurisy in this region; but the question then arose, may not this be a pleuritic friction-sound secondary to a pericarditis which had terminated in adhesion of the two pericar-

dial surfaces, hence synchronous with cardiac movements? How was this question to be settled? The patient was then raised in bed, and examination made over the posterior portion of the chest, when it was found that, on the left side *below* a line corresponding to the lower border of the pericardium, there was absence of vocal fremitus, absence of respiratory murmur, flatness upon percussion, and an abundance of pleuritic friction-sounds; but that, *above* this line the lung moved freely, both posteriorly and anteriorly. This was regarded as safe evidence upon which to exclude pleurisy as being the cause of the friction-sound heard over the præcordial region. On the other hand, if it was a pericardial pleuritic friction-sound resembling a pericardial friction-sound because of adhesions which had been formed between the pleura and pericardium, it was believed to be a safe rule to say that there would be more or less adhesions between the chest-wall and the lung over its *entire surface*, for localized adhesions giving rise to such a result almost never occur.

The diagnosis was, that the man had pericarditis, and at the same time a pleurisy affecting the portion of pleura below the level of the pericardium. The next question which arose was whether the pericarditis depended upon the pleurisy, or was a complication depending immediately upon the rheumatic diathesis. The pleurisy was recognized about *eight* days before the pericarditis, and the pericarditis in the *third* week of the rheumatism, which made it probable that the pericardial inflammation was secondary to the pleurisy, for the reason that pericarditis, if it is to occur, is usually developed within the *first* week of the rheumatism while its manifestations are most vigorous.

The treatment for the cardiac complication consisted of rest in bed, continuance of the anti-rheumatic remedies, and soothing doses of opium.

ANÆMIA.

The case illustrated an important fact, which is occasionally met, but more commonly overlooked, namely, that anæmic persons are not always pale, taking that as the most common symptom of the condition, but they may have a *rosy complexion*. This fact led to the remark that the most reliable indication, one to which there are only a few exceptions, in determining whether anæmia is present or not, is the physical sign known as the *VENOUS HUM*. In the patient before us this sign was well developed.

COMPOUND FRACTURE—DELAYED UNION.

A male patient, *æt.* 55, had received a compound fracture of the leg eight weeks before, which had been treated by the use of the gypsum fenestrated splint, and the point illustrated by this case was the difficulty which sometimes exists in determining whether or not union has taken place.

When there has been no great attempt by nature to repair there is usually no especial difficulty in deciding the question; but when, as frequently happens, nature makes a marked effort, and there is considerable thickening of tissues, it is sometimes exceedingly difficult. In such cases, if the surgeon seizes the limb with his hands close to the seat of fracture, the wrinkling and motion in the skin which will be produced by his efforts will look very much as though motion is present at the seat of fracture; but if he grasps the ankle in one hand and the uppermost portion of the leg in the other, this liability to deception will be avoided. Daily exercise upon the limb was insisted upon, and the union had steadily strengthened.

SYME'S OPERATION—DISTRIBUTION OF THE INTERNAL CALCANEAN ARTERIES AS INFLUENCING THE LINE OF INCISION.

A male patient, about 40 years of age, had his foot crushed between a ferryboat and the dock, and gangrene was developed to an extent that demanded amputation, which was done after Mr. Syme's method. The internal calcanean branches, being distributed to the tissues covering the heel, should be avoided by the knife, if possible, or it is well to do so at least, if the greatest possible chance is to be given to this cushion to retain its vitality. Now a question arises concerning the origin of these branches. Dr. Wyeth, of Bellevue Hospital Medical College, has found that in three-fourths of the cases out of fifty dissections the origin of the internal calcanean branches was *below* the bifurcation of the posterior tibial into the external and internal plantar. Now if the incision in Mr. Syme's operation is made directly downwards, beginning at the front border of the malleolus, and not obliquely, as in the old method of performing the operation, you will have saved the internal calcanean branches which contribute so largely to the vitality of the heel.

FÆCAL ABSCESS—RARE RESULT.

A German woman, æt. 65, was admitted to the hospital July 10, 1875, and gave the following history. Two weeks previous to her admission, while descending the stairs of a stoop, she slipped, fell to the ground, and received quite a number of bruises about the head and face, but had no symptoms referable to the abdomen until about a week after the occurrence of the accident. When admitted she complained of pain over the abdomen, but at the same time endured pretty firm pressure without complaint, and the case was at first regarded as one of malingery. This fact shows how slightly marked the local symptoms were at the beginning. July 12, the patient complained of some pain, and was ordered castor oil, which worked moderately.

On July 19 it was noticed that in the hypogastric region, to the right of the median line, the abdominal walls were raised over a circumscribed space, were hard, and that the elevation gave a *tympanitic* percussion sound. The projecting part was painted with tr. iodine, and covered by a poultice.

July 21.—The swelling was still greater, was tender, gave a tympanitic note upon percussion, and at one point *gurbling* was obtained. The latter was regarded as a novel and unique sign. Abscess of the abdominal wall, with decomposition of its contents, was suspected, and a charcoal and yeast poultice applied.

July 23.—The patient's bowels moved in response to enemata of castor oil and oxgall.

On July 26 her abdomen was increased in size, but in other respects the patient remained in about the condition she had been in for a number of days; the bowels moving after the use of castor oil, and there was no vomiting. On July 27 a copious discharge from the bowels occurred. Over the tumor tympanitic resonance, splashing, and a musical sound were obtained. The patient was ordered castor oil, and morphine sufficient to allay pain.

July 28.—The integument over the tumor was very thin, and it was apparent that an opening might take place at any time. Upon close inspection a pinhole opening was then found, which had permitted the discharge of a very small drop of pus, and it was at once enlarged by making an incision an inch or more in length. A small amount of pus was discharged, gas escaped which had a distinct fecal odor, and when the probe was withdrawn it brought out fecal matter that could

be easily recognized. Through August, as previously, the temperature did not at any time rise to any considerable height above the normal standard.

Sept. 1, the opening had narrowed so as to admit only one finger. On Sept. 25th the opening was entirely closed, and the bowels moved naturally every day. On Oct. 1st it was evident that gas still escaped, but no fecal matter had been seen for a week or ten days.

A spontaneous external opening of an abscess of this character, and a spontaneous closure, is one of the rarest occurrences.

AMPUTATION AT THE KNEE-JOINT.

The incisions in the operation were first a linear one upon the anterior aspect of the limb, beginning a short distance above the condyles, and extending down over the joint, and from the lower extremity two lateral incisions, which nearly surrounded the limb. The flaps were then laid back, the ligaments cut, the joint laid open, and the leg dropped, and then with a catline separated by making a very *oblique* incision through the tissues not embraced in the lateral flaps. The advantage of this oblique stroke is that it leaves the main artery exposed in such a manner that it cannot retract to any great extent, but can be easily secured for the ligature. It was also urged that, when a limb is amputated in its contiguity, the synovial membrane and cartilages of incrustation should be left intact.

PNEUMONIA.

One point to which attention was directed was the treatment to be adopted if a patient is seen when the introductory chill is present, and there is a feeble heart action, as is usually the case in those who are in the use of alcoholic drinks. At once give such patients a drachm or half drachm of chloroform in brandy, or, if chloroform is objected to, eo. spt. of æther in from two to four drachm doses. This was recommended upon the ground that something is required which shall stimulate the heart's action, and the above potion was regarded as the most powerful cardiac stimulant at our command.

RIGHT HEMIPLEGIA—PROGRESSIVE IMPROVEMENT IN THE APHASIA.

This patient, when admitted to the hospital, nearly three months ago, was completely paralyzed upon the right side, both as regards motion and sensation, and there was complete aphasia. There was no loss of consciousness when the attack came on. The interesting feature of the case was, that there had been a progressive improvement in the power of speech, and the patient could talk with considerable ease, although there was yet a good deal of hesitation. This progressive improvement was regarded as an exception to the general rule.

WARM WATER IN SURGERY.

In the treatment of contusions, etc., by immersing the parts involved in warm water, one great inconvenience has been the excessive swelling which usually occurs as the result of the immersion. This can be avoided by a very simple process, namely, freely oiling the parts before suspending them in the water.

In the case before us another fact was illustrated, namely, that the pus covering the surface of a wound becomes coagulated, and in that manner may obstruct a discharge which should continue. It is important therefore to remove the limb from the water occasionally, and syringe out the openings which may communicate with any sinuses or pockets from which pus has been discharging, for it will not be dissolved and removed by the water alone.

CHRONIC DIARRHŒA—CHRONIC DYSENTERY.

A point of distinction between these two diseases was illustrated in this case: and that is, that the most common time for a patient to be *disturbed* by a diarrhœa is at three or four o'clock in the *morning*; while dysentery is better when the patient is recumbent, and worse when he is moving about, and also soon after taking a meal.

CALCIFICATION OF THE LATISSIMUS DORSI MUSCLE.

The history of the case was as follows:—

A girl, *æt.* 8, who had always been healthy, was attacked by diphtheria in December, 1874, which resulted in complete aphonia that continued until April, 1875.

About the first of March she began to experience some difficulty in raising the right arm, which gradually increased, and on the first of May she was unable to raise the arm at all. This fixed position has remained until the middle of September, the date of the present examination. When examined on the first of May a lump was found in the back which was supposed at first to be due to curvature of the spine, but that was soon excluded. Paralysis of the deltoid certainly was expected in a case of inability to raise the arm from the side, especially as the patient had suffered from an attack of diphtheria, but upon close inspection this was eliminated for the following reason. There was found to be a hard plate about three fingers wide extending from the crest of the ilium directly up the back to the lower angle of the scapula, passing over this bone and up along the border of the axillary region and becoming united to the humerus. This hard plate, bony to the touch, was in the exact situation of the latissimus dorsi muscle, and was what held the arm in the fixed position indicated. It was believed to be quite possible that this muscle in the course of the diphtheria became the seat of inflammation, and it occasionally happens that an inflamed muscle becomes the seat of calcareous degeneration. In some cases bone has been found replacing muscular tissue. It was regarded as advisable to anesthetize the patient, and then break off the tendinous attachment to the humerus, and also the adhesions which had taken place over the angle of the scapula. The subsequent treatment would chiefly consist of passive motion.

FRACTURED CLAVICLE—AN OLD METHOD OF TREATMENT REVIVED.

Almost innumerable devices have been employed in the treatment of fractures of the clavicle, but in this instance the broken bone had been permitted to unite without any special dressing. The man, on account of an "unhappiness of the bowels," was kept flat upon his back in bed, and union took place without serious deformity, for the shoulder had been carried by the position of the patient upward, outward and backward very much more than usual when the case is left to nature alone. The result probably would not have been quite satisfactory to a young lady, but it was exceedingly good for a man past the middle period of life.

SYPHILIS SUSPECTED.

The case was one in which there was some doubt as to whether this disease was present or not. This question was determined in the mind of the visiting physician by making firm pressure over the points of junction between the several pieces of the sternum. For, it was observed, the patients will wince when pressure is made over these points when undue tenderness can-

not be detected at any other point in the body, and tenderness also disappears last over these articulations, as the case goes on to recovery.

COMPOUND COMMUNED FRACTURE OF TIBIA AND FIBULA.

The details of dressing in this case are introduced because they vary somewhat from the ordinary method of applying a plaster-of-paris splint in this hospital. A male patient, thirty-seven years of age, six weeks ago fell from a scaffolding thirty-five feet high, and received the injury for which he was admitted. The wound was filled with granulations, but the bones had not united, which was a noticeable feature as illustrating the fact that compound fractures are very much longer in uniting than the simple. The bones had been held in position by dressings more or less fixed, such as side splints, etc., and it was finally dressed in a plaster splint, applied in the following manner: First, two strips of adhesive plaster, two and a half or three inches in width, were placed upon the limb, commencing just below the seat of fracture, and extending for some distance beyond the sole of the foot, and then firmly secured by a roller bandage, which had also been made to cover the foot. A slit was cut in one strip, a short distance from the foot, and the other caused to pass through it, and then the strips were twisted together, thus making a convenient attachment, by means of which an assistant could make extension, and at the same time keep the limb in the proper position while the splint was being adjusted. Next, a piece of an old woollen blanket was laid upon the limb, and the distance measured from the knee along the anterior aspect of the leg and foot, *nearly* to the ends of the toes, and then a strip torn off. This strip was spread over the limb and carefully moulded with the tips of the fingers along down the sides, carefully carrying them around upon either side until they could be brought in contact under and upon the posterior surface. In the crease thus made in the flannel a pencil was carried, which marked the exact line where the cloth should be cut; a fenestra was also marked out around the wound in the soft parts. In this manner a perfect pattern of the limb was obtained by the exercise of only a very small amount of mechanical skill. It is not necessary to carry the blanket around the sole of the foot only sufficient to prevent eversion and inversion.

A second piece of flannel was cut after the first pattern, and the two pieces were all that were employed in making the splint. These pieces were then dipped in water, for two reasons: first, to shrink them; second, because they would take up a larger quantity of the plaster mixture by so doing.

A mixture of plaster-of-paris with water was next made, of about the consistence of thick cream, and the flannels were immersed in it. From this one was removed and spread out smoothly upon a board, the plaster rubbed well into its meshes and then returned to the mixture, and the other piece was then treated in the same manner. The first piece was then spread out smoothly upon the board, and the second applied directly over it. Prepared in this way, they were permitted to remain until the first indications of setting were manifest, when they were quickly applied and moulded to the limb, and secured by a roller bandage. When well set, the bandage was removed and the splint was completed. The shrinkage obtained by first dipping the flannel in water affords a splint which is open somewhat upon the posterior aspect of the limb, perhaps one-sixth or one-eighth of its circumference, which was regarded as a great advantage

gained over the ordinary method of applying this fixed dressing. With regard to the

EXUBERANT GRANULATIONS,

which were fully exposed through the window made in the splint, they were treated as follows: First, an antiseptic preparation was made by taking glycerine and carbolic acid crystals, equal parts, and of this, one part was added to six of linseed oil. A large piece of oakum was then wet with this antiseptic mixture and bound over the wound firmly with a bandage, so as to make a pressure equal with that effected by the splint. In this way a porous carbonized cushion was obtained, that did not adhere to the surface of the granulations, that absorbed the pus and prevented it from working under the splint about the edges of the wound, and at the same time repressed the exuberant granulations. If such a dressing is changed sufficiently often, no trouble need ever be experienced in preventing the discharges from running over the surface of the limb and getting under the edges of the opening in the splint.

CHRONIC VALVULAR DISEASE OF THE HEART.

The following case presented certain points of interest which are worthy of note. A young man, at twenty-three, had been sick "off and on" for three years, but previous to that time had never had any sickness; and had never had articular rheumatism, scarlet-fever, measles, or other disease incident to childhood. The first thing the patient noticed was, that after running at a fire he suffered from palpitation of the heart, and soon after coughed a little and spat up some blood. He claimed that he got well from this attack very soon, and that three months afterwards he again got excited, ran about half a mile, and had a second attack of palpitation and hæmoptysis, from which he also quickly recovered. Six months after the second, he again got excited in dancing, and had a third attack of palpitation and a hemorrhage, which was much worse than either of the preceding, for it laid him up for some time; but he ultimately recovered and went to work feeling as well as ever, except a choking sensation at times and a shortness of breath. The shortness of breath was marked, upon the slightest over-exertion, at the time of examination. Upon physical examination the conformation of the chest was found to be good, respiration somewhat labored, apex beat two inches below and a little to the left of the nipple and accompanied by a slight purring thrill, and a murmur was heard just preceding the first sound, having its greatest intensity over the apex, and ceasing abruptly when the stethoscope was carried to the left more than an inch, or an inch and a half, but was audible over the entire anterior portion of the chest. The very abrupt cessation of the murmur towards the left was its remarkable feature. It also ceased with the beginning of the first sound, and now a student was asked to explain the hypertrophy of the left ventricle which was present. There was no aortic or pulmonic lesion, but it was thought that perhaps there was a tricuspid murmur which could be detected, if the patient were examined under more favorable circumstances. The case was interesting, because it illustrated how a serious valvular lesion may be developed, depending apparently upon an idiopathic endocarditis. Rest was regarded as a great agent in the treatment of such cases, and sustaining the nutrition of the body also as very important.

DR. ROBERT EDES has been appointed Professor of Materia Medica at Harvard Medical School.

Progress of Medical Science.

THE DIFFERENT FORMS OF BRIGHT'S DISEASE.—M. Lancereaux has recently expressed his views on this subject in a paper read before the Association Française pour l'Avancement des Sciences. He observes that since the period of Bright's researches the use of the microscope in the study of renal pathology has led to the discovery of so many different lesions, each of which finds expression in a special group of symptoms, that the name Bright's Disease is no longer a term of precise meaning, as it fails to express any single definite disease as a distinct morbid entity. He therefore proposes the following classification, as more in accordance with the present state of renal pathology:

VARIETIES OF BRIGHT'S DISEASE.

CAUSES.

	Primary.....	{ Gout; lead; congenital contraction of the aorta; arterial lesions.
1. Interstitial nephritis.	Consecutive.	{ Various obstructions to the emission of the urine without vesical suppuration; cancer of the uterus; fibrous tumor.
2. Epithelial or parenchymatous nephritis:		{ Damp; cold; scarlatina; eruptive fevers; diphtheria; cholera.
3. Fatty degeneration, renal steatosis.		{ Alcohol; phosphorus; yellow fever; grave icterus.
4. Amyloid degeneration.		{ Prolonged suppuration; various cachexia.

The interstitial connective tissue, it is observed, has an entirely different origin from that of the epithelial bodies. The latter are derived from the internal layer of the blastodermic membrane, while the former proceeds from its middle layer. These two tissues present a different susceptibility to morbid influences: they are not affected uniformly or simultaneously. Sometimes the disease begins in the connective tissue and sometimes in the epithelial, though after a time there may be a certain mingling of the two processes, so that both tissues will be implicated together. The division into the large white kidney and the small contracted kidney is thought to be insufficient. The interstitial variety is subdivided into primary and consecutive, according to the conditions under which it occurs. In the former the kidney becomes granular, in the latter it remains smooth.

The lesion in interstitial nephritis is in the intervals between the cortical tubules. Little white spots occur in the centre of points of congestion. Fibrous tissue is developed at these points, causing contraction of the tubules and atrophy of the renal tissue. Certain of the tubules undergo a compensatory hypertrophy. In the epithelial variety, the lesion is originally in the epithelium, the interstitial tissue remaining intact. The epithelium becomes swollen, whitish and granular, and the tubes are obstructed. The arterial system is unaffected, and there is no cardiac hypertrophy.

The symptoms of the two varieties likewise present marked differences. In interstitial nephritis the development is slow and insidious. The urine is slightly increased, of a pale hue, and has a specific gravity of 1005 or 1009. It contains a moderate quantity of albumen, and may be of a faint rose-tint. Headache and insomnia ensue, and finally convulsions and death. The fatal termination may be delayed by the intervention of vomiting or diarrhoea, by means of which portions of the excrementitious matters are eliminated from the blood. The duration may be several years. Occasionally, in the latter stages, dropsy occurs. In the epithelial variety the development is sudden and the evolutions rapid. The urine is diminished in quantity; it is dark-colored, and increased in density. Specific gravity 1020. A marked anasarca develops rapidly.

With regard to the third and fourth forms of nephritis, it is observed merely that the renal steatosis is related to the epithelial nephritis, while the amyloid nephritis bears a similar relation to the interstitial nephritis.—*Le Mouvement Medical*, Sept., 1875.

A CASE OF CONGESTION OF THE LIVER WHERE PUNCTURE WAS RESORTED TO, WITH RELIEF OF SYMPTOMS.—A Burmese convict was admitted into hospital on the 19th of June last, with intermittent fever. On the 22d of June, while under the care of Surgeon-Major Blanc, of the Indian Army, he showed symptoms of an affection of the liver, that organ being enlarged and sensitive to pressure, and extending some four inches below the tenth rib. The general symptoms accompanying the affection not moderating, but the swelling increasing, it was resolved in consultation, and relying on the favorable report of Professor Maclean, of Netley, to puncture the liver with the needle of an aspirator. Accordingly, needle No. 2 of Potain's aspirator was introduced into the most prominent part of the swelling, which was three and a half fingers' breadth below the right false ribs, and four fingers' breadth from the median line. About an ounce of black blood was withdrawn, in which were mixed a few pus-corpuscles, as shown by the microscope. The operation afforded the patient undoubted relief, the respiration falling from 34 to 26, though the pulse and temperature were not specially influenced, the latter rising two degrees on the day following, but falling to its former standard on the second day. The liver, however, commenced contracting, and continued to do so for five or six days. About this time general oedema began to make its appearance in the limbs, and becoming general, the patient gradually failed until death occurred, seventeen days after the operation. The autopsy showed that death was due to anasarca, the result principally of excessive fatty degeneration of the heart, while the liver appeared to have nearly recovered its normal condition; so that though the case terminated fatally, the operation was thought to have been beneficial rather than otherwise, the withdrawal of this small quantity of blood relieving the distended hepatic vessels from over-pressure, and so restoring them in a measure to their normal condition.—*The Lancet*, Sept. 25, 1875.

ESMARCH'S APPARATUS SUCCESSFULLY EMPLOYED IN THE TREATMENT OF ANEURISM.—The following case, reported by Staff Surgeon Walter Reid, of the Royal Naval Hospital of Plymouth, illustrates a new application of Esmarch's bloodless system, and seems to recommend itself for its simplicity, safety, and rapid action in facilitating a successful result.

A seaman came under treatment for a sacculated

femoral aneurism of large size and attended with strong pulsation. After a considerable period of rest, while upon farinaceous diet, treatment by flexion of the knee was commenced. Four days later the oedema and severe pain in the limb caused this treatment to be abandoned. Three days later two compressors were applied, one to the main trunk at the brim of the pelvis, and the other at the apex of Scarpa's space. After four hours' continuous compression the pulsation stopped, but soon after returned. Compression was then tried in a variety of ways, but without success. It was finally decided to try Esmarch's system, as more likely than any other plan to produce stagnation in the sac, and so coagulation. The elastic bandage was accordingly applied to the whole limb, but slight pressure being brought to bear upon the aneurism, so in fact as not to compress it. The elastic tubing was then wound around the limb, over the highest turn of the bandage, and then secured. The limb assumed a dusky hue and lost heat, but the aneurism was of its usual size, though not pulsating. After fifty minutes, the patient complaining of pain, the tubing was removed and a compressor (Carte's) applied to the main trunk at the brim of the pelvis. The pulsation which had thus been arrested never returned, even when the compressor was removed, as happened a few minutes later. The collateral circulation appeared then to be established. During that day and the subsequent one, until evening, the patient applied the compressor in an intermittent manner, having directions to remove it for a time when its application gave him pain. The aneurism is now regarded as permanently cured, though the appliance was put in use on the 11th of September last. The writer believes that the success of the treatment depended on the stagnation of the blood, which induced coagulation; though possibly other influences, such as the loss of heat and the condition of the tissues, so nearly resembling death, may have contributed to the same result. In extending this idea, he thinks it may be admissible to inject fluids into the sac to induce coagulation when the limb is thus rendered bloodless.—*The Lancet*, Sept. 25, 1875.

TREATMENT OF EMPYEMA.—Prof. With says that though collections of fluid in the pleural cavity are often cured by nature, the assistance of art is, nevertheless, generally necessary. In selecting the mode of operation it is important to make an accurate diagnosis between those cases where there is considerable serum and but little pus, as well as in those where the pus is greatly in excess of the serum. In the former cases the collection is to be removed by puncture, and the puncture hermetically sealed; in the latter by incision, with subsequent drainage. Both operations should be performed antiseptically, that is, in a carbolic acid atmosphere, using a carbolic acid water-spray.

Finding that, notwithstanding every precaution, the percentage of fatal cases was very great, and that it was impossible to prevent the decomposition of the pus, Prof. With has for two years made use of injections of quinine solutions into the pleural cavity, after removing the pus, and has succeeded in saving all his cases of primary empyema. The sulphate of quinine is to be injected in doses of from one to one and a half grammes daily. The discoloration and unpleasant smell of the discharge is soon changed under this treatment. The fever diminishes, and the patient's strength and general condition improves. As this progresses, the dose and its frequency is correspondingly diminished.—*Hospitals-tidende*, Aug. and Sept., 1875.

STATE EXAMINATIONS FOR THE DEGREE OF DOCTOR OF MEDICINE.

AMONG those physicians who take pride in their profession, and are anxious to see its ranks filled by only worthy men, there is a growing desire to have the power of granting degrees taken from the medical schools and placed in the hands of men who will be free from school interests, jealousies, and prejudices. If the schools were endowed, and the professors paid a fixed salary, independent of the number of students in attendance, the result would probably be that no better and stricter examiners could be found than the professors themselves. The rivalry between the schools would then spend itself in endeavors on the part of each to graduate the most thoroughly trained, the most skilful, and the best informed physicians. This is the case at the present time with the best literary colleges in the country, which are in large measure endowed. They are constantly raising the standard of admission, and rendering the curriculum better adapted to the wants of the student. The endowment of medical colleges in this State, however, is a thing of the not very near future. One or two of the schools, it is true, are making efforts to secure such an endowment; but surely the most sanguine friends of these institutions must confess that it will probably require years still of patient and persevering labor for the realization of their hopes. On the other hand, how is the standard of requirements for graduation to be kept at a uniform height if one or two only of the seven medical colleges in the State are strict in issuing diplomas to their students. The endowment, therefore, of one or two of our medical schools, however desirable for the interests of higher medical education, will not accomplish the result for which all earnest physicians hope, viz., the establishment of a uniform and reasonably rigid standard of requirements for receiving the degree of doctor of medicine.

As this question has been thoroughly discussed in all its aspects by a committee of the American Medical Association, not to mention the scores of essays and editorials that have been devoted to it, we must confess at the outset some fear lest our efforts to solve the difficulties will prove as unsuccessful as those just alluded to. The medical profession, however, has too deep an interest in its own welfare and reputation as an organic body to let so serious an evil as that which the present system of examination involves continue, without making renewed efforts to remedy it. It is with this object in view that the following scheme of a plan for State examinations for the degree of doctor of medicine has been prepared. The chief points only are given, and these are stated in the briefest possible manner, as otherwise the article would necessarily have to be of considerable length:

Examination of candidates for the degree of doctor of medicine; fees.—All candidates for the degree of M.D. to be examined by a State Board of Examiners. Previous to the examination they are to pay a fee of twenty dollars, and to furnish the examiners with satisfactory testimonials regarding age, course of studies pursued, etc., etc. The actual conferring of degrees to be done by the colleges in the usual manner, the wording of the degree simply being changed to conform to the new régime.

Places and times for examination.—Examinations to take place during February in New York, Albany, Syracuse, and Buffalo; during September in New York and Syracuse.

Number of examiners needed.—There should be seven examiners, one for each of the following departments of medicine:

1. Anatomy. 2. Physiology. 3. Chemistry and Materia Medica; Hygiene. 4. Pathology and Practical Medicine. 5. Surgery. 6. Obstetrics and Gynecology; Diseases of Children. 7. Pathological Anatomy.

Remuneration of the examiners.—The examiners should be paid not less than \$25 a day during actual service. The mode of management of the fund accruing from candidates' fees to be determined by the State Medical Society. Whether the service should last for several years or only for one year, will also have to be determined by the State Society.

How shall the examiners be appointed?—The examiners should be appointed in part by the colleges themselves, and in part by the State Medical Society. This can be effected through a committee of appointment, to consist of fifteen or sixteen men—one from each of the seven medical colleges, and the remaining eight or nine chosen by the State Society. This committee to meet during the session of the State Society, and to select seven men (and seven substitutes), who shall constitute the State Board of Examiners for the degree of Doctor of Medicine.

This outline sketch covers, we believe, the most important features of the scheme. Hitherto the great

obstacle to the inauguration of any kindred reform has been the powerful influence brought to bear against it by the medical colleges. Their fear has been that the work would not be carried out with thorough impartiality, and that consequently they would have nothing to gain and probably something to lose by the change. In the present plan the aim has been to throw upon the colleges a large share of the responsibility for the selection of good examiners. Their representatives would constitute a strong minority of the committee of appointment, and upon them would probably devolve in the main the duty of suggesting the names of suitable candidates for the positions in question. Hence it might reasonably be expected that, if such a plan were carried into effect, the colleges would withdraw their opposition.

There are many points of interest connected with the details of such a system of State examinations to which we may refer at another time.

Reviews and Notices of Books.

VISION: ITS OPTICAL DEFECTS, AND THE ADAPTATION OF SPECTACLES. By C. S. FENNER, M.D.

This is a work of three hundred pages, printed in excellent large type, and on thick, creamy paper, and, as a specimen of the publishers' care and attention to details, is worthy of high praise.

It is divided into three parts: the first is a short and incomplete chapter on physical optics, as preliminary to the study of the second part on physiological optics. The third and largest part is devoted to the discussion of the errors of refraction and defects of accommodation, and the adaptation of spectacles.

The author has not succeeded in making this a popular treatise, the very nature of the subject making that a difficult task. The arrangement of the contents of the book is very faulty, and woefully deficient in system. The marks of the scissors and paste-brush are plainly evident all through the work, and it may be fairly said that the work of compilation has not been well done. The editor has not taken the trouble to fill up the gaps in his structure, or endeavored to make it a homogeneous whole. In quoting authorities, he mentions Stellwag, but entirely ignores the American edition of his work. The illustrations are generally good, and the execution of them excellent. While we have an English translation of Donders' immortal work upon the Errors of Refraction and Accommodation of the Eye, we have always an authority to whom we can turn for both instruction and entertainment; and in view of this, one is tempted to ask why this compilation of Dr. Fenner was published. Still it may be of use to the general practitioner, if the latter can supply the gaps in the discussion of physical and physiological optics, which detract so much from the value of the work.

M. BOULLAUD has resigned his chair as Professor of Clinical Medicine in the Faculty of Paris.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 13, 1875.

DR. F. DELAFIELD, PRESIDENT, IN THE CHAIR.

OSTEO-MYELITIS OF THIGH—REMOVAL OF NECROSSED BONE AND RECOVERY.

DR. MASON presented a specimen of osteo-myelitis, which he had removed from a boy six years of age, who entered Bellevue Hospital, November 9, 1874. His previous history was not very satisfactory. Indeed it was difficult to find how long before he went to the hospital that he began to suffer, or in what way he had received the injury. One account was, that some days before entrance, he fell down a flight of steps, while another history was, that the patient had been struck on the inside of the knees.

When he entered the hospital he was suffering intense pain. His leg was flexed upon the thigh and the thigh upon the pelvis. His temperature was 103° F. For the first five days he suffered a great deal from delirium and sleepless nights. At first there was no swelling, but the limb was intensely painful to the touch. It was not until some days had elapsed that the swelling took place, extending from the knee to just below the trochanter. On the 23d of November fluctuation was detected just over the inner trochanter. An incision was made at this point and a considerable amount of pus was evacuated, together with some clots of blood. At this time the patient had a severe attack of synovitis, which threatened to go on to suppuration.

In order to counteract the flexed condition of the limb, it was straightened out and subjected to a weight and pulley. In the meantime sinuses had formed in the neighborhood of the joint, and were discharging pus.

On January 7th a swelling was noticed two and a half inches below Poupert's ligament. This was opened and pus was evacuated. A seton of oakum was then passed from this opening to the one previously made. This was in turn removed and the tract thoroughly syringed with carbolic-acid water. The discharge continued to be quite profuse, and his health suffered more or less in consequence, so that at one time the temperature was 104.

On February 15th, when the house-surgeon was dressing the limb, he noticed that a fracture of the thigh had taken place, at the junction of the upper and middle thirds. Previous to this there was a good deal of thickening and hardening all along the limb, which was thought to be due to an involucrum, and at the consultation it was thought that this involucrum had been fractured. The patient's condition did not admit of an operation, and he was kept as still as possible by means of extension. On February 25th the upper, just below Poupert's ligament had closed.

On April 1st a consultation was held in his case, when it was decided to remove what dead bone could be found. The operation was performed on the 3d of April, but instead of involucrum, nothing was found but thickened periosteum, inside of which was contained five and a half inches of necrosis detached from the epiphyses. The dead bone was removed and the limb treated in the ordinary way by plaster-of-paris bandages.

The patient did remarkably well after the operation, so that by the 28th of May the wound had entirely closed, and by the 19th of June he was able

to walk without crutches. The case was regarded as one of osteo-myelitis, the periosteum being secondarily involved.

The patient was exhibited to the Society. He had good use of the lower extremity, and very considerable motion at the knee-joint. The shortening was an inch and an eighth.

MYOSITIS OSSIFICANS.

DR. V. P. GIBNEY presented the following account of a case of myositis ossificans:

The subject of the present history is a female *et. ten years*. She presented herself for treatment at the Hospital for Ruptured and Crippled, out-door department, May 22, 1875, and a hasty examination revealed nothing save an apparent right scoliosis, for which a brace was ordered. On returning from my vacation I saw her again, September 14th, and the mother called my attention to a small "lump" over her right scapula. It felt like an exostosis; I traced it, however, to the humerus, where the latissimus dorsi is inserted, and found that the arm could be raised from the side over an arc of only 30 or 40 degrees.

The hardened mass, triangular in form, was at the same time discovered in the right lumbar region, one side of the triangle being continuous with the spinal column, the process of which were in a vertical line without any lateral duration. I had Dr. Janeway in consultation, and he suggested myositis ossificans. Subsequently the scapular muscles, same side, were found to participate in the ossific process. Prior to December, 1874, the child was perfectly well. Had diphtheria, which was followed by paresis of vocal cords. Convalescence delayed. The mother is unable to fix the date of beginning of ossific process, except that in the early spring she noticed a stiffness when the child attempted to bend forward.

While under my observation no decided changes have taken place. The scapular muscles do not feel so hard as the others involved. I am curious to see whether the disease will progress, and hence operative interference is postponed. The muscles thus far affected are latiss. dors., erector spinæ and scapulari, all on right side.

Rindfleisch speaks of it as a true bony change, and likens it in all respects to the "drill bone" noticed in the recruits of the Prussian service. These growths, eighteen cases of which have been observed, occur over the left arm at the insertion of the deltoid muscles. The cause of this was obvious. In the article on Diseases of Muscles, Holmes' System of Surgery, is a report of a very extensive case in St. George's Hospital, under the care of Mr. Cesar Hawkins. Blistering repeatedly seemed to afford the most relief. In the Museum of the College of Surgeons, London, is the skeleton of a man in whom nearly all the muscles of the back had become ossified.

DR. JANEWAY remarked that this was the first extensive deposit of the sort which he had seen. The point of interest, however, rested in the treatment which suggested itself, viz.: the breaking up of the bony insertions of the latissimus dorsi so as to free the right arm. At the same time this was done a portion of the bony material could be obtained for microscopic examination.

DR. KNAPP referred to a case of a woman, aged 30, in whom the majority of the muscles of the upper part of the body were perfectly stiff. The case had been described by Prof. Von Dusch. Although the disease had existed for twenty years it was still progressing.

DR. HEITZMANN stated that he had experimented upon young dogs by means of lactic acid, and had suc-

ceeded in causing the absorption of the bones to the extent of producing rachitis and osteo-malacia. He believed that it would prove a remedy for extra bony growths, and suggested its trial in the case presented.

DR. JANEWAY suggested that the use of lactic acid might tend to reduce the legitimate bony structure, but not affect the new growth.

DR. KNAPP did not think this a reasonable objection, inasmuch as it was well known that foreign deposits yielded first to such remedies.

DR. JANEWAY presented a small specimen, accompanied with the following history, prepared by Dr. Van Vorst.

Samuel A. Jones, 36, single, a native of U. S., porter. Family history unknown. Has been accustomed to drink. Has had specific disease and secondary manifestations.

He was admitted to Bellevue Hospital, Aug. 28th, 1875, complaining of a feeling of coldness, followed by profuse sweating, which would occur every day, about nine o'clock in the morning. Never had a distinct chill. He felt himself becoming weaker and saw that he was much paler. Lungs and heart normal. Liver and spleen were not examined at this time. Urine, sp. gr., 1014, acid, no albumen; a microscopic examination revealed nothing. Quantity normal.

Patient took to the bed on admission. He was placed on large doses of quinine and tinct. of the chloride of iron.

At the end of two weeks there was no improvement. He was becoming more anæmic and weaker. Temperature and pulse both normal. Diarrhœa occurred, but was easily controlled.

Patient continued in this condition, but growing weaker and more anæmic, until a week before his death, when he complained of "an oppression" in the epigastrium. An examination could not reveal any tumor in this situation, nor very marked tenderness. The liver was enlarged, but nothing like hard nodules could be detected. Three days before death Dr. Janeway examined him, and found the liver, and also the spleen, slightly enlarged. He also examined the blood, but found no increase of white globules. Pulse, respiration, and temperature were normal at this time. Urine, sp. gr., 1016, acid, no albumen. Quantity normal.

On Sunday, Oct. 3d, he was seen at the usual visit, about nine o'clock, and made no complaint of feeling worse, or of suffering any pain. At 11 o'clock A.M. the house-physician was called to him, the orderly stating that he had awoke, from a sound sleep, complaining of intense pain in the epigastric and left hypochondriac regions. House-physician found him in a profuse perspiration, pulse 120, respiration 34. He was perfectly conscious, and said "he knew he was going to die." No paralysis existed. Pupils normal. Ten (10) minims of Magendie's solution of morphia were given hypodermically, and hot cloths placed over the site of pain. In ten minutes he said he felt easier. At this time one of the visiting physicians arrived, and the house-physician left patient, thinking that as the pain was relieved, there was no pressing need of his remaining. On his return at the end of an hour he was told that patient had died. From the accounts of the patients in the beds near him, there were no convulsive movements, but death took place suddenly.

On post-mortem examination the brain, heart, and lungs were normal. The liver was markedly enlarged, and scattered throughout the whole of its substance were numerous whitish gray points, from the size of a pin's head to a marble. The lobus spigelii was almost

filled with them, half of its substance being so occupied. They produced no induration on the surface. On cutting through the deposit there was a moderately firm resistance, but no whitish juice exuded.

The spleen was found to be half of its normal size, softer than natural, and in its substance was a slightly whitish-looking deposit here and there. The mesenteric glands were slightly enlarged, as was also the case with the lumbar glands. Peyer's patches, the solitary follicles, in fact, all the other glands of the body, were normal.

A microscopical examination of the liver revealed a new formation, composed of round lymphoid cells, arranged in a reticulum growing in the connective tissue surrounding the portal. The spleen was not examined. This lymphomatous tissue also occupied the substance of the kidney. The marrow of the femur was red, but contained very little fat.

In conclusion, Dr. J. spoke of the difficulties attending the diagnosis of this case, the usual signs of the disease being either absent, or so modified in relation to each other as to be of negative value only. It was quite evident from the autopsy that the spleen did not claim that amount of attention that was usually its due.

DR. DELAFIELD asked if he (Dr. J.) felt very confident about the changes in the bone-medulla, as that tissue varied very much in the appearances which it presented in health.

DR. JANEWAY said that scarcely any adipose tissue was discovered, and the oil globules were so conspicuously absent, that but four or five appeared on the microscopic field at one time, the remainder being made up of round cells, and reticula and red globules and vessels. He doubted not that many of these cases were called cancer of the liver; in fact, he had seen one such case which might have been diagnosed thus, except for the increase in the white blood-globules.

A short discussion was then held by Drs. Beverley Robinson, Janeway, and Delafield in regard to the diagnosis between leucæmia and pseudo-leucæmia; after which,

Dr. Post presented a specimen of lipoma. It was removed from the shoulder of a man, aged sixty years, and had been growing for nine years. The points of special interest connected with it were: 1. That the integument over the mass had ulcerated, giving rise to frequent hemorrhages. 2. That there were large and tortuous vessels over its surface, giving it the gross appearances of a malignant growth; and, 3. That there was more than the usual pseudo-fluctuation present. The growth weighs 5½ pounds.

DR. DELAFIELD had seen one large lipoma in which the conditions of ulceration and hemorrhage were present.

DR. KNAPP, in this connection, referred to a large tumor of the kind, situated in the upper part of the back, while in another case in which a tumor was so situated as to invite severe irritation, neither ulceration nor hemorrhage took place. The latter case presented itself at Langenbach's clinic, and the tumor occupied the sacral region, hanging over the buttocks like an apron, being half a foot long and one foot broad, and being in the same position as the usual fashionable female ornaments now worn.

DR. LEWIS SMITH presented the brain removed from a male adult, aged fifty-two years, who came into Charity Hospital on the 24th of last month. At that time he was complaining of a dull pain in the occiput, and also in the lumbar region. These were his only symptoms, with one exception—a slight paralysis of his

right arm, right leg, and left side of the face. This paralysis was not such as to prevent his walking about. His symptoms not being very marked, not much attention was given to his case, and he was simply kept quiet.

On the 5th of the present month he thought that he had sufficiently recovered to air himself in the grounds with the convalescents. While there, and about one o'clock in the afternoon, he was suddenly seized with a convulsion affecting the right arm and leg and the muscles on the side of the trunk, and those of the right side of the face. These convulsions were not marked, but rather like those of paralysis agitans. He was taken back to his bed, when these convulsions continued at short intervals, during most of the afternoon.

At two P.M., one hour after the seizure, the temperature was taken. In the right axilla it stood at 107¼°, while on the left it was 103¾°. There was a difference then of four and a quarter degrees in favor of the right (partially paralyzed) side. In order that no mistake could be made, the temperature was again taken an hour afterwards, when it was found that the right side gave 108° (the convulsive movements continuing), while on the opposite side it had made a proportionate increase, being 104°. This difference was proportionately during the whole duration of the case.

At 4 P.M., Dr. Smith made his usual visit, when the patient was found to be passing into a comatose state. The convulsive movements were then very feeble, and the pulse was 120. The pupils had been dilated most of the time, but were at times contractile. The patient expired two hours later.

The autopsy was made 20½ hours after the convulsive seizure. On removing the calvarium nothing unusual save a little flattening of the cerebral convolutions was observed. This condition was most marked on the left hemisphere near the vertex. At the base of the brain most of the arteries were in an atheromatous condition, their calibre being very much diminished thereby. On opening the lateral ventricles about three ounces of straw-colored fluid escaped from each. The posterior portions of these ventricles were much distended. On slicing the brain, in both hemispheres, but more particularly in the posterior and middle lobes, and also in the corpus striatum and thalamus opticus, were found numerous points in which were cysts, varying in size from a kernel of wheat to a pea. The brain substance had been absorbed to make room for these new growths. In the substance of the pons varolii there was found one of these cysts of considerable size.

It was expected from the symptoms, that an artery had been ruptured, and that death had been occasioned by extravasation. Such a clot, although of the size of half a chestnut, was found in the left corpus striatum, but this was probably produced by the obstructed circulation, consequent upon the convulsive movements already noted. At all events, this clot did not seem large enough to cause the death of the patient.

The liver was cirrhotic and the kidneys were atrophied and fatty. There did not appear to be much general softening of the brain substance.

The points of interest were, 1, the disparity of temperature between the two sides; 2, the cause of death; and, 3, the cross-paralysis.

DR. JANEWAY remarked that the atheromatous arteries in the first place produced a fatty degeneration of portions of the brain, and were in all probability the starting points of the phenomena noticed.

A SECOND EXAMINATION OF A TUMOR OF THE TESTICLE.

DR. C. HEITZMANN exhibited microscopical specimens of the tumor of the testicle, which was extirpated in November last year by Dr. H. B. Sands, and presented at the time to the Society. At that time Dr. Delafield, who examined the tumor, called it a compound adenoma. Dr. H. did not agree with that diagnosis, and stated his reasons for so doing:

By comparison of healthy testicles with the tissue of the tumor it becomes evident that no new formation of glandular (tubular) tissue took place during the development of the tumor, though many tubuli are enlarged, and partly even transformed into cystic cavities. The main part of the tumor is built up by an indifferent tissue, which looks like marrow of bone or cartilage, the elements of which are round or spindle-shaped. Between the elements there is a hyaline, but scanty basis substance, quite analogous to that of marrow. We then have to deal in this case with a kind of tumor, termed by Virchow "round and spindle-cell sarcoma." Imbedded in the sarcoma we find islands of hyaline cartilage, of the size of a hempseed to that of a pea, provided with large multinucleated cartilage elements. Besides the cartilage we see on a few places portions of new-formed bone, which lay close to the islands of cartilage, partly lined by marrow elements, which, when filling up the bays of the bone, show the character of multinucleated protoplasmic bodies, so called "myeloplaxes." Tumors of this kind usually grow fast, and are liable to metastatic deposits in different organs of the body, being of a very malignant nature.

DR. DELAFIELD remarked that in regard to the point of a new formation of glandular tissue, it was a question which had been raised ever since the first of these tumors had been examined. These composite tumors of the testicle reaching a large size, and composed of different kinds of tissue, had always excited the attention of pathologists. The question in the case in hand was whether the tubules were old or of a new formation. A great many different opinions were found on both sides of the question. The tumor in question had shared the usual fate of being open to suspicion, but Dr. D. was satisfied that a new growth of glandular tissue was present, as he had carefully compared them with the appearances of the old tubules in the same specimen.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 21, 1875.

DR. S. S. PURPLE, PRESIDENT, IN THE CHAIR.

THE RHEUMIC DIATHESIS IN DERMATOLOGY.

DR. H. G. PIFFARD read a paper upon this subject, in which he discussed eczema, psoriasis, pityriasis, as belonging to a common diathetic condition to which he had given the name *rheumic*. He had given it this name because, first, it implies an exudation; second, because the blood condition probably is similar, if not identical with that which gives rise to rheumatism and gout; and third, because the vulgar name salt-rheum embraces these affections, and indeed rheums or rheumes is a name which has been frequently used for the diseases under consideration.

There are three important points to be studied in connection with the rheumic diathesis.

1. With regard to its veritable existence.
2. As to its nature; and

3. As to whether the affections assigned to it really came within its influence.

The existence of this diathesis cannot be considered as positively proven. We are able only to form an opinion from a preponderance of probabilities, and, in addition, the concurrent opinion of many able observers in this country assist in establishing it. With regard to the nature of the *rheumic* diathesis, it is not a mere matter of theoretical interest, but an important question when considered from a therapeutical standpoint. The views of the older writers regarding the essential causes of cutaneous affections are of but little value. Nor have the views entertained by various writers of the present century been very clearly formulated. By one class of observers the diseases included in the rheumic category depend upon the same constitutional conditions which give rise to rheumatism and gout. Others regard them as due to retention of urinary elements in the blood. Others, that they are due to a peculiar vice of constitution, of the exact nature of which we are ignorant. Others, that they are sometimes due to the presence of oxalates in the system, etc. The various opinions expressed, however, by those who argue for a constitutional origin, are one in idea, as all agree that they are due to the presence of some *materies peccans*. The views of the author of the paper harmonize substantially with those stated, and may be formally stated thus. They are affections which pertain to an accumulation or excess of excrementitious substances in the blood, and presumably in an accumulation of those which are efficient in the production of gout and rheumatism. The following are the principal noxious agents, viz.: Uric, lactic, and oxalic acids, creatine, creatinin; there may be others. Some of these substances are derived from the albuminoids which have been introduced into the system; others are obtained sometimes from the albuminoid and sometimes from the amylaceous and saccharine substances introduced.

The general process by which the albuminoid, amylaceous, saccharine, and other substances are disposed of in the system is probably one of oxidation. For instance, the albuminoids may be introduced in the form of food, and finally leave the body as urea; and now if the oxidation of the received albuminoids is incomplete, the result is an increased proportion of urea in the system as the result of sub-oxidation. This incomplete oxidation is to a certain extent normal, and it is only when the substances which result from it accumulate unduly that they prove harmful. Such an accumulation occurs whenever renal action is deficient. Over-accumulation may also occur from over-production, and is probably more frequently due to this cause than to deficiency of excretion. When more than the normal amount of products are obtained as the result of an over-supply of peptones, they are left in the blood to be excreted. The kidneys now being unable to completely carry off all this surplus material, other organs are called in to assist, and the skin is the one which notably manifests efforts in that direction. Reference was here made to the doctrine advocated by Murchison, namely, that the liver is the principal organ which carries on the process of oxidation in the body, and that a deficiency in the action of this organ is the real source of the sub-oxidation which gives rise to these noxious elements. This doctrine the author was inclined to adopt. A pound of beef was then traced from the mouth to the renal discharge. Now, if the processes by which it is transformed into tissue, or, having subserved its purpose in the animal economy, the processes by which the disintegrated tissue is removed by the

kidneys—if these processes are arrested, the excrementitious materials seek exit through some vicarious channel, and this in part is furnished by the skin.

The presence of alkalies in the system favors oxidation, and this has an important therapeutical bearing upon the diseases in question.

In answering the third question, namely, whether these affections properly belong in the same category, it is necessary to consider some of their more prominent features. They possess certain characteristics which suggest a mutual relationship, for they have the following features in common: They are not contagious, are frequently general, usually chronic; natural duration is infinite; two or more forms may be present at the same time; do not always preserve their individual characteristics; relapses are frequent; they all itch; are always superficial, and are all more or less amenable to certain definite methods of treatment which have but little or no effect upon other diseases.

With regard to the

TREATMENT,

the object must be to counteract or modify the diathesis. It is embraced under two heads, namely, rational and empirical. We have the blood surcharged with noxious material, and the accumulation is due either to deficient action of the kidneys or to an overproduction of this material; and there are strong reasons for believing that the liver is the organ which fails to bring about the proper oxidation of material introduced into the system. These are among the considerations which have a bearing upon the therapeutics, and perhaps are the most important. We have, therefore, to deplete the blood in order to remedy what has been left incomplete in the process of oxidation, and this is done by acting upon the bowels, kidneys, and skin. Care must be exercised in acting upon the kidneys, for they may be in a condition in which stimulation will aggravate rather than improve the difficulty. We are therefore obliged to rely, in many cases, chiefly on the action which can be produced upon the skin and bowels in the fulfilment of the indication. To this end the hot-air or Turkish bath may be resorted to with great benefit, and it may be repeated daily without harm. To act upon the bowels cathartics of various kinds may be used, salts and senna answering an excellent purpose, so as to give one or two loose evacuations daily. Active purgation, as a rule, is not required. Mineral waters may be employed with benefit.

If the kidneys are healthy the bowels may be left entirely, and diuretics administered. Among these remedies wine of colchicum, infusion of digitalis, balsam copaiba, propylamin, carbonate of lithia, and Vichy, are the most serviceable, and may be used singly or in combination. The prolonged use of alkalies should be broken by one or two days of intermission each month.

With regard to the question of *oxidation*, if the deficient oxidation occurs because of the introduction of an excessive amount of the albuminoids, etc., the proportion should be diminished by regulating the diet. Hence it may be well to cut off, to a greater or less extent, the use of meat, and substitute for it bread and vegetables. If there is scarcely the requisite ability to take care of a small supply of nitrogenous food the deficiency may be made up by the inhalation of pure oxygen gas, or better, oxidized oxygen. Certain remedies may also be used which are said to liberate their oxygen very readily, such as the chlorate of potash. Finally, if the liver is functionally inactive, cer-

tain drugs may be used which are said to stimulate the function of this organ, such as mercurials, podophyllin, etc. Arsenic, which has so long had an enviable reputation in the treatment of these affections, was regarded, upon the whole, as being much less satisfactory as a plan of treatment than the plan of treatment just marked out. Local treatment is of service in almost every case, but was left to be considered in connection with each affection.

The paper being open for discussion,

DR. L. D. BULKLEY remarked that the views set forth in the paper read by Dr. Piffard corresponded almost precisely to those which he had held for some time; and that he was all the more pleased because Dr. P. and himself had arrived at about the same conclusions after having studied the question independently.

The doctor referred somewhat at length to a paper which he had published in the Archives of Dermatology, in April last, on the Relation of the Urine to Skin Diseases. He did not, however, fully accord with the French view of the arthritic and herpetic diathesis; nor fully concur with the doctrine taught by Murciison respecting the function of the liver, and objected to the term *rheumic*, because we already have a sufficiently large group of synonyms to indicate conditions which are identical or at least very nearly so.

DR. KEYES remarked that he recognized a constitutional diathesis underlying a large number of skin diseases, but that he was not quite prepared to adopt in full the French doctrine. He did not believe that persons who habitually have an excess of oxalate of lime or uric acid in the system are specially liable to skin diseases, for if so, every patient who has an oxalic calculus should have an eczema or some other cutaneous eruption, but such is not the case. He was of the opinion that the facts mentioned in support of the French doctrine were very pretty in theory, but was not, from observations made in actual practice, inclined to accept the doctrine in full. Probably patients who have rheumatic and scrofulous tendency will have different forms of eczema; but at the same time he did not feel inclined to be bound down by a diathesis of any kind. He was of the opinion that the diseases under consideration are much more commonly dependent upon internal than upon external causes, but yet does not feel quite willing to accept as a demonstration the views put forward. There is a tendency in many persons, generally an inherited one, to have eczema, psoriasis, etc., and it is doubtless true that if a person has no such tendency it is almost impossible to produce these diseases; but now having a peculiar condition of system the external circumstances may develop the diseases in question. It is possible that rheumatic antecedents may be a more common cause than any other.

DR. JOEL FOSTER mentioned citrate of potash as a very serviceable alkali to be used for rendering the urine alkaline, because it is rapid in its action, and does not destroy the appetite as most alkaline preparations do.

DR. STURGIS was of the opinion that local causes play a very important part in the development of skin diseases, and that entirely independent of diathetic conditions. Such local causes as irritating ointments, scratching with the finger nails, etc., may develop very troublesome cutaneous affections, entirely apart from constitutional conditions. He did not regard the mere presence of uric or oxalic acid in the system as the cause of skin eruptions; for if that is the light in which the doctrine is to be placed, every person who suffers from these deposits most, would be most liable

to have eczematous eruptions, etc., but such is not the fact.

He was of the opinion that uric acid was not decidedly increased in eczema. There was no doubt but that eczema and rheumatism are associated in the same individual, but he should hesitate considerably before ascribing the cutaneous disease to the constitutional affection. It is also a fact well established that locally applied stimulants and irritants will produce an eczema that will resist internal treatment continued for a long time, but will yield rapidly to an appropriate local treatment. He did not refuse, however, to acknowledge that a constitutional tendency very often plays an important part in the etiology as well as in the treatment of skin affections.

DR. J. C. PETERS favored the diathetic doctrine.

DR. B. ROBINSON felt persuaded that there are forms of these diseases which are due to local causes; but, on the other hand, there are others which evidently are dependent upon a diathetic condition, and in the treatment of which local measures are not sufficient to effect a cure. Local applications may cure for a while, but they are almost certain to return after a varying length of time.

DR. BULKLEY mentioned the importance of keeping the healthy portion of the skin in good condition, for the purpose of affecting the diseased portions. For instance, a localized acne may be very much benefited by general baths and frictions.

DR. KEYES favored the use of baths and frictions not so much for favoring the escape of excrementitious matters through the skin as to stimulate the general and local circulation. The idea of keeping the pores open he did not give much credit to, for the reason that he believed they usually were in this condition, and required but little attention in that direction.

DR. PIFFARD remarked that it is not the discharge of large quantities of uric acid or oxalic which entered into the formation of calculi, etc., but that it is the lack of discharge of these substances which gives rise to skin diseases.

The discussion being closed the Academy adjourned.

ENGLISH MEDICAL PRACTICE.—At the opening of Westminster Medical School of London, Dr. Davy, in delivering the introductory, said concerning the payment and honors conferred on medical men: "Their salaries were simply miserable; hospital physicians and surgeons were for the most part unpaid; poor-law officers most piteously; surgeons in the service, very badly, and young practitioners not at all. For seven years' hard work at the St. Marylebone Dispensary he had received one guinea; and a very distinguished London assistant-physician had found that his salary equalled that earned by the man who put the skid on the 'bus wheels at Holborn Hill. The lecturer had been taught how dignified the profession was. In his opinion the British public introduced far more largely the element of impudence than dignity into practice."

Finally, and for their encouragement at the entrance of their career, Dr. Davy told the students that their early prospects in life were most disheartening. Their toil and ambition might be equally great, but their pay and dignity would be equally small. They had to deal with an ignorant and proud people, and he advised every one to resign at once any and every thought of becoming a medical man, unless he possessed three qualifications: first, independence; second, an aptitude for and love of the profession; third, the readiness to pay a heavy premium in this world for his prospect of reward in the next.]

New Instruments.

CHAIN-SAW CONDUCTOR.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: Practical surgeons are familiar with the difficulty encountered in conducting a chain-saw around a deep-seated bone where it becomes necessary to perform the operation of excision. The writer's experience on a recent occasion of this sort led him to devise an instrument that might obviate the difficulty. The instrument represented by the accompanying figure is the result of his efforts, and is now offered to the profession to be tested by experience. The instrument itself is already familiar as an efficient agent with which to work a track around a deep-seated bone. It consists of a thick blade curved flatwise at its extremity and set in a stout handle. The concave surface of the blade is flat, and sharp at both edges and at its rounded extremity; its opposite surface is bevelled off like a chisel at the edges as well as the extremity. It hugs the surface of the bone and works a track for itself by displacing the investing tendinous and aponeurotic structures. By a simple addition to this instrument, a ligature may be attached to its extremity after it has made the circuit of the bone, and on its withdrawal the ligature follows in its track, and then after being attached to the chain-saw conducts it to its place. This addition consists of a longitudinal crest raised to the height of one-eighth of an inch upon the convex surface of the blade near its extremity,

where a notch is cut in it looking obliquely towards the handle.

The mode of employing it is as follows: After working a track around the bone the instrument is held *in situ* while a loop of twine engaged over the nail of the forefinger meets the end of the instrument and hitches the loop in the notch. The instrument is then withdrawn and the ligature follows it.

Respectfully,

GURDON BUCK, M.D..

46 West 29th Street.

September 29th 1875.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Oct. 24th, 1875, to Oct. 30th, 1875.

GREENLEAF, C. R., Assistant Surgeon.—When relieved by Assistant Surgeon Dickson, assigned to duty as Post Surgeon at Nashville, Tenn. S. O. 156, Department of the South, Oct. 21, 1875.

WOODHULL, A. A., Assistant Surgeon.—When relieved by Assistant Surgeon Delany, assigned to duty at Oglethorpe Barracks, Savannah, Ga.

BROWN, J. M., Assistant Surgeon.—Assignment to duty at Fort Wood, N. Y. II., revoked, and assigned to duty as Post Surgeon at Fort Wadsworth, N. Y. II. S. O. 213, Mil. Division of the Atlantic, Oct. 22, 1875.

DELANY, A., Assistant Surgeon.—Assigned to duty at McPherson Barracks, Atlanta, Ga. S. O. 156, c. s., Department of the South.

DICKSON, J. M., Assistant Surgeon.—When relieved by Assistant Surgeon Woodhull, assigned to duty at Huntsville, Ala. S. O. 156, c. s., Department of the South.

BYRNE, C. B., Assistant Surgeon.—Assigned to duty at Fort Brown, Texas. S. O. 201, Department of Texas, Oct. 23, 1875.

SKINNER, J. O., Assistant Surgeon.—Granted leave of absence for two months, and on its expiration to report to the Commanding Officer, Yorkville, S. C., for duty as Post Surgeon. S. O. 33, Department of the South, Oct. 23, 1875.

COMEGYS, E. T., Assistant Surgeon.—When relieved by Assistant Surgeon Brown, assigned to temporary duty at Fort Hamilton, N. Y. II. S. O. 213, c. s., Mil. Division of the Atlantic.

NAVY.

October 25.

SCOFIELD, W. K., Surgeon.—Detached from the receiving ship *Ohio*, and ordered to the *Wabash*.

LOVERING, P. A., Assistant Surgeon.—Detached from the receiving ship *Ohio*, and ordered to the *Wabash*.

October 31.

DUVAL, MARIUS, Medical Director, is ordered to special duty at Baltimore, Md.

Medical Items and News.

TRIPLETS, ETC.—DR. JOHN LAMBERT, of Salem, Washington Co., N. Y., writes: Seeing an imported case of triplets in last issue of RECORD, perhaps you may be glad to notice one in my own practice.

July 26th, I delivered Mrs. T. Reid, of this place, at her 8th confinement, of triplets: two boys seven pounds each, one girl six pounds. First boy presented knees, the second boy head, and the girl breech. Pains severe and exhausting, expulsive force slight. Each child required manual or instrumental delivery. Placenta appeared to be one, though disposed of before I had opportunity carefully to finish the examination of it.

There were three distinct cords and amniotic sacs; membranes required to be ruptured in each case.

No untoward symptoms. Mother and children have done well until within a few days. I fear the boys will perish from cholera infantum, which is now prevailing in a fatal form in our midst.

I also notice an interesting case of kidney disease.

In July, Dr. Irwin, an intelligent physician at West Hebron, brought me specimens of kidneys recently removed from a child three years old at death. The doctor had only seen the case once in March, being called to make a hasty post-mortem as he was passing a short time previous to the funeral, and he was unable to procure a satisfactory medical history of the case. Body greatly emaciated. We found two large "tumors," one in each hypochondriac region, which he removed and found them to be the kidneys, the right one weighing plump four (4) pounds and the left one weighed two and three-fourths ($2\frac{3}{4}$) pounds. Dr. J. R. Ward, of Troy, has kindly furnished me the following microscopical examination.

"The specimens of kidney sent me are of extreme interest on account of the excessive character of the

changes which have occurred in it. In certain portions, it seems to be in a state of cirrhosis, an interstitial fibrous exudation, having crowded out nearly all traces of healthy structure. The greater part of the specimen, however, consists of cheesy masses, which seem to have resulted from tubular inflammation and fatty degeneration, oil granules, corpuscles and epithelium being massed in scanty connective tissue. Portions of tubes covered with cells are occasionally visible."

UNIVERSITY OF MICHIGAN.—Out of one hundred and thirty-five applicants for admission to the Medical Department of the University of Michigan twelve were rejected on preliminary examination.

THE LATE DR. E. KRACKOWIZER.—At a Stated Meeting of the New York Academy of Medicine, held October 21, 1875, a committee, consisting of Drs. A. Jacobi and Gardon Buck, presented the following resolutions, which were unanimously adopted:

Resolved, That in the decease of Dr. Krackowizer the Fellows of the New York Academy of Medicine have sustained the loss of one of their most eminent and highly esteemed associates. Eminent for his thorough and extensive professional acquirements, his varied experience and mature judgment, his practical skill and brilliant success, especially as a surgeon. Esteemed for his honorable and upright character, his unvarying trustworthiness, his cordial and friendly bearing, and his self-sacrificing loyalty to duty.

Resolved, That we will cherish his memory as a bright example of professional rectitude and private virtue worthy of our constant emulation.

Resolved, That a copy of these resolutions, duly authenticated, be communicated by the Secretary to the family of the deceased, with the expression of our sympathy in their great bereavement.

Resolved, That these resolutions be published in the Medical Journals of this city.

S. S. PURPLE, M.D., President.

W. T. WHITE, M.D., Secretary.

PANCREATIN.—At the last annual meeting of the American Pharmaceutical Association a paper, in answer to the following query, was read by Professor E. Scheffer: "Is Pancreatin Converted into Pepton when it is Digested with Acidulated Pepsin?" The writer stated that he was enabled by his experiments to assert positively that pancreatin, when brought into the stomach, became destroyed; and that it, therefore, could have neither physiological nor therapeutic effect when administered internally.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.—The annual meeting of this association begins at Baltimore on November 9th, and will continue four days.

THE CORRESPONDENT who signs himself "X" will secure the publication of his letter by sending us his name.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

[THE MEDICAL RECORD is published every Saturday. Notices of meetings, lectures, operations, etc., intended for publication in this bulletin should be received at the office, 27 Great Jones Street, one week previous, to insure their appearance.]

Wednesday, Nov. 10th.—N. Y. Pathological Society, at Col. of Phys. and Surg., 23d st., cor. Fourth av.

Thursday, Nov. 11th.—N. Y. Public Health Association.

Friday, Nov. 12th.—Medical Library and Journal Association, 107 East 28th st.

Original Communications.

REPORT OF THE FIRST RECORDED
OPERATION INVOLVING THE REMOVAL
OF THE ENTIRE ARM, SCAPULA, AND
THREE-FOURTHS OF THE CLAVICLE.

By DIXI CROSBY, M.D., LL.D.,

LATE PROF. OF SURGERY IN THE DARTMOUTH MEDICAL COLLEGE.

REPORTED BY HIS SON,

A. B. CROSBY, A.M., M.D.,

PROF. OF SURGERY IN DARTMOUTH MEDICAL COLLEGE, AND PROF. OF
ANATOMY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE."The evil that men do lives after them.
The good is oft interred with their bones."

SHAKESPEARIAN commentators, mindful, doubtless, of the loving principle, "*Nil de mortuis nisi bonum*," have been inclined to transpose this sentiment. They tell us that this was not the real opinion of the "Bard of Avon," but was expressed in the case of Caesar, for a purpose, by Mark Antony, as he faced an angry populace. Nevertheless, when we recall the large number of strong men in our profession who have labored intelligently and successfully for half a century and more without leaving any of the fruits of their vast experience on record, we are forced to the conclusion that "the good is oft interred with their bones."

The operation, the report of which I now put on record, was performed in March, 1836, thirty-nine years ago, by my lamented father, the late Prof. Dixi Crosby, M.D., LL.D., of the Dartmouth Medical College. This for me is a loving tribute, which I place upon the grave sacred to his memory. For him, it is simply the payment of a debt which he owed to his favorite art,—an art which he cultivated with extraordinary success for half a century.

It is to me a source of never-ending regret that my father's aversion to writing prevented him from recording, for the good of the profession, the life-long experience of an exceptionally large surgical practice, and the matured opinions of an original mind, observing, fertile in expedients, and which never shrank from the gravest responsibility.

In making up a record of this case, I have availed myself of the scanty notes made by the operator himself.

A former pupil of my own, Dr. S. W. Davis, who has practised his profession for some years in the town where the patient resided, was kind enough to get for me, in 1868, from surviving members of the family, as well as from neighbors present at the operation, various important facts in the case.

Fortunately, several persons, both medical and non-medical, who were present at the operation, are still living, and have given me such facts as they have been able to recall. From these data, and a comparison of them, I have made up a history of the case, which I believe to be reliable in all essential particulars.

Jonathan G. Cummings, the subject of this report, was born in Plymouth, Grafton County, New Hampshire, Aug. 7, 1800, and died July 6, 1838. He was by occupation a farmer, and at times followed the business of a stage-driver. During the first thirty years of his life he was unusually rugged and healthy. The record in the family Bible states that the father of the patient died with typhoid fever, although, accord-

ing to the record, he had suffered from "a cancerous humor" for thirty years. The patient's grandfather, three uncles, and one aunt died with cancer. A cousin died from the same disease, and another was suffering from the same affection in 1868, when Dr. Davis procured these facts. None of the brothers or sisters died with cancer.

Some time in 1833 or 1834 the patient drove his coach into Plymouth late at night, and while waiting for his horses to cool off, having previously wrenched his shoulder, fell asleep, with his arm hanging over the back of a chair. On awakening at daybreak he found his arm numb and almost powerless; nor did it ever return to a perfectly natural condition. On the contrary, he suffered pain in the right shoulder, which persisted for two years, gradually attaining great severity, until it was at length constant.

About this time a hard tumor made its appearance on the anterior aspect of the shoulder, over the articulation. The tumor steadily increased, until it attained the size of a water-pail. It was so large that a slight inclination of the head brought the patient's cheek in contact with the tumor. The circumference of the mass, measuring antero-posteriorly over the shoulder and beneath the axilla, was thirty-seven inches.

The patient consulted Dr. R. D. Mussey, who at the time occupied the chair of surgery in the Dartmouth Medical College. Dr. Mussey diagnosticated the case as "*osteo-sarcoma*," but considered the operation too formidable to be undertaken, and therefore declined it. Dr. Amos Twitchell, of Keene, N. H., another distinguished surgeon, examined the patient, confirmed Dr. Mussey's diagnosis, and concurred in the impracticability of the operation. Dr. John C. Warren, of Boston, gave a similar opinion.

Meantime, the disease had involved the humerus, scapula, and clavicle. The immense mass began to degenerate, and in January, 1836, several openings formed, from which a thin, sero-sanguinolent fluid escaped. After this the pain diminished, but the discharge rapidly increased. A cavity formed, which was estimated to be about as large as a two-quart basin. There were twelve openings on the antero-superior aspect of the shoulder communicating with this cavity. Through these there was a copious discharge resembling colloid, but mingled more or less with pus, blood, and degenerated osseous tissue. The openings finally coalesced, forming one large one, about five inches in diameter. The discharge now ranged from a pint to a quart in the twenty-four hours. The opening being at the upper part of the cavity, the debris could only be removed by raising the body of the patient up erect, and then bending the trunk far forward until the contents were evacuated. On one occasion the whole osseous framework gave way, leaving the arm hanging by the integument, muscles, etc.

Meantime, the patient was confined to the house. He lost appetite and flesh, until he was reduced to the last degree of emaciation. It was believed that the patient could not long survive. It was found, however, that the cavity could not be readily evacuated on account of the opening being at the top of the tumor. My father was requested to see the patient, and either make an opening at the most depending part of the cavity, or else sever the arm so that the dressings could be made more satisfactory, and the patient's comfort be subserved. My father suggested to the patient that a ghost of a chance was better than no chance at all, and advised him to have a radical operation attempted. The patient gladly submitted; but fully realizing the terrible and immediate risk, he made his

will, partook of the sacrament, and resigned himself to the knife.

I find no definite record of the operation among the operator's brief notes. Dr. Andrew McFarland, for many years the accomplished superintendent of the Illinois State Hospital for the Insane, was a student of my father, and witnessed the operation.

In a communication, dated Dec. 5, 1868, Dr. McFarland writes as follows: "The incidents of the operation are marvellously distinct in my mind. Cummings was a stage-man on a route from Plymouth to Concord. In bridling a horse, some months before the disease appeared, he had wrenched the shoulder, and the disease, which we then used to term '*osteosarcoma*,' was the result, involving both the scapula and clavicle. The disease was very far advanced before it came under your father's notice; and his decision in regard to the operation, and also his performance of it, were both *immediate*. The patient, a middle-aged man, was at the house of his father, in Plymouth village. Dr. Samuel Rogers was his attendant. There were present at the operation, besides Dr. Rogers, Dr. Long, of Plymouth, Dr. Wright, of Holderness, and Dr. Whipple, of Wentworth. Your father was attended by his retinue of students—Garland, T. R. Crosby, Arrias (a German Jew from Paramaribo, S. A.), and myself. The nurse of the patient was a Mrs. Willoughby, whom I remember chiefly for the noiseless quietude of her step in contrast with her perfectly elephantine proportions. The subclavian artery was controlled by the handle of a large key in the hands of Dr. Whipple. Dr. Wright managed the sponges. Dr. Long, then in ill health, was a spectator. The incision was the length of the clavicle; but what direction the lines took over the scapula I do not remember. I do not recollect whether the whole clavicle was taken away, but think it was. The hemorrhage was comparatively slight.

The operation was a perfect success,—very little of the incisions but what healed by the first intention; and from the time of the operation in March, till June, the patient changed from the extreme stage of emaciation to an avoirdupois of nearly two hundred. He came before the New Hampshire State Medical Society in June, greatly rejoicing in the respite he had got even then."

I may add to this record, that the operator himself stated that he isolated and tied both the subclavian artery and the subclavian vein before dividing them. The whole tumor weighed twenty-five pounds after removal. Dr. Geo. W. Garland, a distinguished medical man, of Lawrence, Mass., who read his profession in my father's office, was also present at the operation.

Under date of Dec. 22, 1868, in response to my inquiries, Dr. Garland wrote me a letter, from which I quote the following: "The operation was simply awful: no ether, patient attenuated to the last extremity, with eyes sunk in their orbits, face lean, rough, and wild in its expression; at every touch of the knife gave a look of agony not equalled in its effect on those who witnessed it by even the sardonic grin of death itself. So frightful was the whole scene, and so affecting, that when the operation was concluded there was no one in the room but your father and myself. The operation was commenced with the expectation that the neck of the scapula and arm only need be removed; but on opening the joint freely, it was obvious that the entire scapula must be removed, or the operation be abandoned. After a moment's conference Dr. Crosby proceeded to remove the scapula, and the outer three-fourths of the clavicle. The flaps were antero-posterior, and I think covered the exposed

surface. Owing to his extreme leanness, the motion of the ribs during respiration was an anatomical expression worth the seeing. Of the subsequent treatment I have no definite recollection, only that it was wholly sustaining."

All accounts agree that the shock following this operation was terrific. The operation and dressing of the wound consumed thirty minutes. At the end of the first fifteen minutes the patient lost consciousness, and became pulseless, with cold extremities, etc. He did not become fully conscious for twenty hours.

Mr. Samuel C. Heath, a neighbor who watched with the patient on the night following the operation, says: "I sat up that night. He was delirious most of the time. Stimulants were freely used,—twelve to sixteen ounces of whiskey being given him during the night. The next day he appeared much better, and from this time gained strength rapidly. He began to sit up within two weeks, and got out of doors in some seven or eight weeks after the operation."

In June following the operation, Cummings was to all appearance a healthy man. The cicatrix was fifteen inches in length, and seemed entirely free from induration. During July, however, the disease recurred in the cicatrix, and the tumor soon attained the size of a large tea-cup. This was removed by my father some time in August, and the wound cicatrized in the most amiable manner.

As a proof of the patient's entire recovery, it is remembered that in the autumn following the operation he cleared three acres from bushes, and sowed it with rye. In the winter another tumor, not quite as large, developed in the cicatrix, and was removed early in 1837. No more tumors appeared, and in the following summer he was able to carry on his farm, working most of the time. He remained fleshy and in perfect health for a year. In April, 1838, he was seized with an attack of paraplegia, from which he suffered until July 6th, when he died. The principal operation in this case was performed early in March, 1836, and the patient survived until July 6, 1838,—a period approximating two years and four months. No autopsy was obtained, but my father always entertained the opinion that the paraplegia was due to a malignant deposit about the lumbar spine. In reviewing the literature of the subject, I find that operations involving the removal of the arm, scapula, and clavicle are of comparatively recent date, and the number limited.

Dr. Stephen Rogers, of New York, published in the *American Journal of Medical Sciences* for 1868, a tabular statement of excisions of the scapula, which covered all similar cases to that which I have narrated. This admirable table* of Dr. Rogers, which has been extensively quoted in English and German works, is believed to cover all recorded cases of a similar character up to 1868. Dr. Otis, of the Surgeon-General's office at Washington, has investigated all subsequent cases that have been recorded, and I am happy to acknowledge my indebtedness to both these accomplished surgeons for the material which they have placed within easy reach of my hand.

I shall briefly enumerate the operations involving the removal of the arm, scapula, and more or less of the clavicle, in their chronological order. Several instances are on record where the entire arm and scapula were removed; but these do not come into the category of operations similar to the one I have just recorded, as the clavicle was left, and I therefore omit them.

* This table, with authorities cited, and additional cases, was published in the *New York Medical Journal* for February, 1870.

1836.—D. Crosby, then living at a town now known as Laconia, N. H., removed the entire arm, scapula, and three-fourths of the clavicle, at one operation, for an enormous *osteo-sarcoma*. Patient entirely recovered, and died with paraplegia twenty-eight months after the operation.

1837.—R. D. Mussey, then living at Hanover, N. H., reported in the *American Journal of Medical Sciences*, 1837, vol. xxi., p. 390, an operation involving the removal of the scapula and clavicle for malignant disease. Nineteen years before, he amputated at the metacarpus, and six years previous to the last operation, at the shoulder-joint. The patient was forty at the last operation, and thirty years afterwards he was living and in good health.

1838.—Amos Twitchell, of Keene, N. H., removed the entire arm, scapula, and part of the clavicle for malignant disease, but never reported it. His accomplished nephew, Dr. Geo. B. Twitchell, writes me as follows in regard to his uncle's operation: "I can only say that he did remove the entire scapula, arm, and part of the clavicle at one operation, in the winter or early spring of 1838. I came to study with him in June, 1838, and the operation was performed a few months previous. I have frequently heard him speak of the operation. It was perfectly successful, so far as the operation was concerned, but the patient died some six months afterwards of the malignant disease.

G. McClellan removed from a boy of seventeen the scapula, arm, and part of the clavicle with a fatal result. The case is reported, and the preparation figure in McClellan's *Principles and Practice of Surgery*, Philadelphia, 1848, p. 412. Dr. McClellan claimed that his operation was the first of its kind in the history of surgery,—a claim which, as I have shown, was not well founded.

Getani Bey, in the *Memoirs of the French Academy of Medicine*, describes a disarticulation of the shoulder, with extraction of the scapula, and resection of the clavicle, in the case of a lad of fourteen years, who recovered. This operation has been erroneously ascribed to Larrey.

1842.—Prof. Rigaud removed scapula and outer end of clavicle eight months after amputation at the shoulder-joint. The disease was *osteo-sarcoma*, and the patient remained well three years after last operation. This case was published in the *Strasburg Medical Gazette* for 1844.

1860.—Niepce removed left arm, scapula, and clavicle from a man thirty years of age, injured by machinery. The patient recovered, and the case is reported in the *Bulletin of the Academy of Medicine*, 1864-5, vol. xxx., p. 723.

A. Lucke, in the *Archives of the Surgical Clinic*, vol. iii., p. 306, published in 1862, relates that Prof. B. von Langenbeck, having exarticulated the humerus in the case of a man twenty-three years of age, on the recurrence of the disease extirpated the scapula and an inch and a half of the clavicle. The disease was *osteo-sarcoma*, and the patient survived eighteen months.

W. Busch removed the scapula and part of the clavicle from a young girl whose arm was previously amputated for cancer, and the patient recovered. This case is reported in *Lehrbuch der Topographischen Chirurgie*, 1864, Abth. iii. s. 19.

1863.—J. Syme removed from Mr. K——, aged forty, the arm, scapula, and portion of the clavicle. This case is reported in *Syme's Brochure*, entitled "Excision of the Scapula," Edinburgh, 1864, p. 30.

1864.—G. Buck removed the scapula and part of the clavicle, the arm having been removed by a previous operation. The patient recovered from the opera-

tion, but died from a recurrence of cancer some months afterwards. An account of this case was published in the *N. Y. Medical Journal*, 1869, vol. viii., p. 440.

Also, 1863 and 1864.—J. S. Bird, in the *Lancet*, 1868, vol. ii., p. 696, reports the case of Ellen L——, injured by a fall, in whom two operations were performed in 1863-4. The head of the humerus, the entire scapula, and part of the clavicle were removed.

1867.—Sir W. Fergusson removed from a man forty years of age, the arm, scapula, and part of the clavicle. A tumor, resulting from an injury, rendered the operation necessary, and the patient died on the third day. The case was published in the *Medical Times and Gazette*, 1867, vol. ii., p. 465; also in the *Lancet*, 1867, vol. ii., p. 552.

1869.—P. H. Watson reports in the *Edinburgh Medical Journal*, 1869, vol. xv., p. 124, "an amputation of the scapula, along with two-thirds of the clavicle, and the remains of the arm."

These are all the cases involving the removal of the arm, scapula, and more or less of the clavicle, that I have been able to derive from the very extended researches of Drs. Rogers and Otis, which I am inclined to think have been nearly if not quite exhaustive in the premises.

From these records, it would seem that my father is entitled to the credit of priority in this operation; and it is certainly creditable to his pluck that, called to do only a slight palliative operation, he decided on the instant to do a new and capital operation in surgery. The fact that three eminent surgeons had decided the operation to be impracticable, and the desperate constitutional condition of the patient, would have intimidated a young surgeon possessing less confidence in himself. This was, however, characteristic of the operator. My father did almost all of the great operations in surgery before seeing them done, and repeated them many times, with exceptional success. It is a remarkable fact that the three first operations of this nature were done within two years by New Hampshire surgeons.—Crosby, Mussey, and Twitchell,—in the order in which their names have been enumerated.

In all the cases cited save two, not over three-fourths of the clavicle was removed. The majority of the operators have seemed to prefer retaining that portion of the clavicle which gives origin to the outer head of the *sterno-cleido-mastoid* muscle. In Niepce's case, however, and in that of Getani Bey, the whole clavicle was removed, although Niepce's operation was done for an injury, and not disease.

If I have seemed to be unnecessarily prolix in reporting my father's case, the society will, I am sure, pardon it,—first, because the report was of necessity made up from many diverse sources; and second, because my heart was warmed with filial devotion in this grateful task, all the details of which have seemed to bring back

"the touch of a vanish'd hand,
And the sound of a voice that is still!"

APPOINTMENTS.—Dr. Charles F. Parkes has been elected to the chair of anatomy in the Rush Medical College, and Dr. H. A. Johnson has been made Professor of Clinical Medicine in the Chicago Medical College.

NEW YORK OBSTETRICAL SOCIETY.—At the stated meeting of this Society, held Nov. 2d, Dr. T. Gaillard Thomas was elected *President*; Dr. A. Jacobi, *First Vice-President*; Dr. C. C. Lee, *Second Vice-President*; Dr. Paul F. Mundé, *Recording Secretary*; and Dr. Emil Noeggerath, *Corresponding Secretary*.

INTEMPERANCE AND DIPSO MANIA AS RELATED TO INSANITY.

By EDWARD C. MANN, M.D.,

MEDICAL SUPERINTENDENT STATE EMIGRANT INSANE ASYLUM, WARD'S ISLAND, NEW YORK.

[Read before the meeting of the "American Association for the Cure of Inebriates," held at Hartford, Conn., Sept. 28, 1875.]

In accepting an invitation to read a paper before you to-day, I do so fully conscious that most of the gentlemen composing this Association have had far greater opportunities for studying this specialty than I have enjoyed. I shall, therefore, briefly present the subject to you as it has appeared to me during my connection with the asylum which I have the honor to represent. I think it impossible to estimate the complex influences that intemperance exerts upon the production of insanity, and different authorities differ very much in their opinion on this subject. All agree, however, that it is intimately connected with and is one of the main causes of insanity. Lord Shaftesbury, in his evidence before the Select Committee on Lunatics, in 1859, expressed his opinion that fifty per cent. of the cases admitted into English asylums are due to drink. This is a rather large estimate, but many superintendents of foreign asylums have estimated the admissions from intemperance at twenty-five per cent or higher, including not only the proximate but remote cause of the disease. This percentage will be largely increased if we take into account the great number of cases in which the intemperance of parents causes the insanity or idiocy of their offspring. I have traced intemperance as a cause in almost every case of general paralysis that has fallen under my notice, and others have observed the same thing. M. Lunier estimates that fifty per cent. of all the idiots and imbeciles to be found in the large cities of Europe have had parents who were notorious drunkards. Out of 350 insane patients, admitted during two years at Charenton, in Europe, insanity was attributed to drink in 102 instances. I think, from my examination of the statistics of all the insane asylums, both here and in Europe, that it is not too much to say, that fully one-fourth of all the admissions are due, either proximately or remotely, to intemperance.

I pass now to the consideration of dipsomania, as a form of physical disease—as insanity.

Dipsomania has been aptly defined as "an uncontrollable and intermittent impulse to take alcoholic stimulants, or any other agent, as opium, or hashish, which causes intoxication—in short, a methomania." We must distinguish between this and the physiological state, in which the individual merely chooses to indulge in liquor to excess. The great question of importance is to distinguish the two states or conditions, when the result, intemperance, is the same. We must observe whether there are symptoms in our patient which can be referred to primary disease of the nervous system. We must examine for hereditary influences, which, when present, lead us, of course, to suspect disease. Early development of the appetite for stimulants points in the same direction; but the great diagnostic point attending the disease, is the irresistible impulse by which the patient is impelled to gratify his morbid propensity, being, during the paroxysm, blind to all the higher emotions, and pursuing a course against which reason and conscience alike rebel. It is frequently seen that these paroxysms are preceded by considerable disturbance of the nervous system. The patient perspires and is sleepless, uneasy and prostrated, and so craves some stimulant.

Between the paroxysms he is different from a common drunkard, in oftentimes disliking exceedingly all stimulants, and is then a useful member of society. Dipsomania has been described under three forms: acute, periodic, and chronic. The acute form is the rarest, occurring only after exhausting diseases or excessive venereal indulgence. The periodic form is much more frequent, and is observed in persons who have suffered injury to the head or spine, females during pregnancy and at the catamenial period, and also in men whose brains are overworked. This form is frequently hereditary, and consequently proportionately difficult of cure. These patients may abstain for weeks and months from all stimulants, and may, during this interval, positively dislike them. At last, however, the patient becomes uneasy, listless, and depressed; is not inclined to apply his mind; and, finally, begins to drink, and continues until intoxicated. It is an interesting and rather remarkable fact, that with this class of cases, as Charles Lamb, in his "Confessions of a Drunkard," pertinently remarks, "to stop short of that measure which is sufficient to draw on torpor and sleep, the benumbing apoplectic sleep of the drunkard is to have taken none at all. The pain of the self-denial is all one." The patient continues this course for ten days, or perhaps a fortnight, and then bitterly regrets his fall. This often runs on, if not checked, into mania, and lapses into dementia. The last and most common is the chronic form; and I have always found this to be the most incurable form of the disease, as the patients are incessantly under the irresistible desire for alcoholic stimulants. I think the latter class of cases require constant seclusion in an asylum, if they wish to be free from intoxication, as a discharge or leave of absence is always followed by a repetition of the same acts. In a majority of cases of this nature, we find hallucinations of sight and hearing, which oftentimes produce very painful moral impressions, and at times even great terror in the patient. Cases of delirium tremens are excluded in these remarks. These patients manifest confusion of thought, perversion of feelings, suicidal tendencies, tremors of the facial muscles and tongue, anæsthesia of the extremities at times, and very often paralytic symptoms, going on to general paralysis. The subject of hereditary metamorphosis of the diseases of the nervous system is of great importance in this connection. As a result of intemperance in the progenitors, we find transmitted to the offspring all, but different forms of neuroses. It may be dipsomania, epilepsy, chorea or actual insanity, or a proclivity to crime. It is, at all events, an aptitude for some form or other of nervous disorder, the particular form being often determined by causes subsequent to birth. The law of hereditary transmission applies equally to the victims of dipsomania as well as to the other insane classes, and is to be studied, I think, in three divisions, according as it is manifested. First, in predisposition or simple aptitude, the result of a defective organization and a weakened or diseased nervous system, as a result of which, the possessor is predisposed, or has a tendency, to seek for the relief obtained by alcoholic stimulants when laboring under physical or mental depression; second, in the latent state or germ of the disease; and, third, in the actually developed disease. The first of these states, the predisposition or aptitude, being hereditary in a strong degree, is universally acknowledged to be the most difficult to eradicate, and requires the wisest sanitary conditions adapted to both mind and body. Most people doubt the existence of the second or latent state or germ of the disease, ignoring the law of progressive development, and such persons find it

difficult to believe that dipsomania coming on in maturity, as a result of ill-health, mental shock, etc., may have originated in intemperance in the parent or grandparent. Yet this is a fact. One very important organic law, which should be universally understood in this connection, is, that morbid impulses and characteristics and traits may disappear in the second generation and break out with renewed intensity in the third, although a tendency or predisposition may be transmitted to the offspring, and, under good hygienic and other favorable circumstances, die out and fail to be transmitted any further. I have remarked in my experience with the insane, whether the exciting cause be intemperance or something else, that the cases most unlikely to recover are those where the insane temperament or diathesis is clearly manifested, and where the predisposition to disease is inherited. Such patients, although they may have lucid intervals, rarely if ever entirely recover. I think the insane impulses to drink, which overcome all the efforts of the individual who inherits a tendency in this direction, present the same indications for treatment as do the suicidal and homicidal impulses, namely, seclusion from society and the necessary restraint, in an asylum.

I do not agree with that class of persons who hold that under all circumstances the dipsomaniac is to be treated as an invalid, with the utmost gentleness and forbearance, and then, with the strangest perversity, turn round and tell you that inebriety is no excuse for criminal actions, and fine and imprison the unhappy man who has been driven into the debauch by an irresistible craving for drink, when properly he should be regarded as insane, and should be sent to an inebriate asylum for treatment and cure. Our laws at present fail lamentably in preventing intemperance, and this is due in a great measure to the false view in which this disease is held by the judiciary. The different forms of dipsomania correspond in their manifestations, and oftentimes in their causes, to other cases of mental disease, and cannot properly, I think, be separated from them as regards the fact of the disease. Dipsomania often appears as a result of the same causes that operate in the production of other types of mental disease, such as ill-health, severe mental shock, blows on the head and spine, and sunstroke.

We are dealing in both cases with abnormal cerebration; in the one case associated with mania, melancholia, dementia, and idiocy; and in the other, with a depraved alcoholic appetite—an irresistible impulse which the mind seems powerless to control; an insane impulse, just as surely as a homicidal or a suicidal impulse is an insane impulse. I think that when our cerebral pathology, which is as yet in its infancy, becomes more generally understood, it will be found equally applicable to this as to other forms of insanity. The terrible insane craving for alcoholic stimulants is often the result of a lowered vitality or abnormal organic development of the nervous system that has descended from generation to generation, gaining in intensity until it manifests itself by the complete loss of self-control and active inebriety in children and grandchildren, after they once taste intoxicating liquors and indulge in them. The blunted moral perception which so many inebriates exhibit, and which renders them peculiarly liable to a relapse after they leave an asylum, is to be regarded in the same light, I think, as the perverted moral sense in moral insanity.

In every institution for the insane, we find inmates who exhibit no obvious intellectual aberration or impairment, the moral faculties being deranged, while the intellectual faculties remain apparently in their normal condition. The manifestations of moral insanity

may be a simple perversion of some sentiment or propensity, under certain exciting causes; and I think this exactly comprehends cases of dipsomania with loss of self-control and perversion of the moral sense. The person, of course, is aware that the act is wrong in both instances, but the control which the intellect exercises over the moral senses is overborne by the superior force derived from disease. I have been told many times, by both insane patients and dipsomaniacs, that the feeling on the one hand to commit some insane deed, and on the other to give way to alcoholic appetite, was contemplated in both instances with horror and disgust, and at first successfully resisted, until at last, having steadily increased in strength, it bore down all opposition. What can be a more powerful argument in favor of the disease theory of dipsomania?

Pathology of Inebriety.—The basis of our cerebral pathology is the fundamental principle, that healthy mental function is dependent upon the proper nutrition, stimulation, and repose of the brain; and upon the processes of waste and reparation being regularly and properly maintained. We know that the cerebral cells are nourished by the proper and due supply of nutritive plasma from the blood, and that this is essential to healthy function; and, indeed, the ultimate condition of mind with which we are now acquainted consists in the due nutrition, growth, and renovation of the brain-cells. If now we take into the system an amount of alcohol that causes the blood plasma to convey to the brain-cells a noxious and poisonous, in place of a nutritive substance, stimulating the cells so as to hasten the progress of decay and waste beyond the power of reparation and renovation, and impressing a pathological state in them, we must inevitably have resulting a change of healthy function, and a certain amount of disease induced. Owing to the abuse of alcohol, we have resulting a change in the chemical composition of the cerebral cells from the standard of health, which is the foundation of organic disease, as it prevents and interrupts healthy function. As a result of the overfilling of the cerebral vessels or hyperæmia of the brain from the long-continued use of alcohol, we have at first symptoms of irritation, due to increased excitability of the nerve-filaments and ganglion-cells of the brain. The symptoms of exhaustion and depression occurring at a later stage are due to lost excitability of the nerve-filaments and ganglion-cells of the brain, owing to a want of the proper supply of arterial oxygenated blood to them. This is caused by the excessive cerebral hyperæmia, the escape of venous blood from the brain being obstructed; the result being that no new arterial blood can enter the capillaries. We may have apoplectic or epileptic attacks and paralysis occurring in the course of these cerebral hyperæmias, and they may be due either to obstructed escape of venous blood or to secondary œdema of the brain, in which transudation of serum takes place into the perivascular spaces and interstitial tissue of the brain, with consequent anæmia.

We know comparatively little yet respecting the physiology and pathology of the nervous system; and consequently comparatively little information has been gained regarding the morbid changes that take place in the brain and its appendages, as a result of the abuse of alcohol. Such knowledge in this direction as we do possess, shows that analogous changes take place in chronic alcoholism and chronic insanity—namely, atrophy and induration of the brain, and thickening and infiltration of the membranes. The nerve-cells have also been found to be the seat of granular degeneration in some instances, and some histologists have claimed to have discovered fatty degenera-

tion of the various brain elements. Respecting the latter changes, Dr. J. Batty Tuke, of Edinburgh, who is one of the most successful of modern investigators in the department of morbid cerebral histology, gives it as his opinion that the application of the various tests for oil will fail to detect the presence of the so-called "free oil-globules" in the substance of the convolution, which he considers to be but the scattered débris of granular cells. According to the great pathologist, Rokitsansky, we find thickening and increase of volume of the pia mater and arachnoid, and permanent infiltration of the former and a varicose condition of its vessels, as a result of continued abuse of alcohol. As the state of the pia mater is unquestionably closely related to the higher functions of the brain, the latter must suffer more or less as the result of such an abnormal condition of the former. If there exists a permanently congested and thickened state of the pia mater, it is extremely probable that if it becomes suddenly turgid and hyperemic as a result of severe emotional disturbances, we shall have, resulting from the increased pressure on the brain, coma, epileptiform and apoplectiform attacks, and other grave nervous symptoms. It is fair to conclude that in the majority of cases the first changes that occur are repeated attacks of active cerebral congestion, followed by chronic cerebral congestion and chronic cerebral meningitis; and that, as the disease assumes a chronic form, the brain takes on a secondary change and becomes anæmic, atrophied, and indurated—a state allied to cirrhosis. In these cases of chronic meningitis, proceeding to atrophy and induration—of which I have seen quite a number—the prominent symptoms have been impairment of memory, dullness of intellect bordering on dementia, trembling of the limbs, tottering gait, hesitating, slurring speech, and other symptoms indicative of gradually progressing paralysis. In two cases of general paralysis due to drink, in which I made a post-mortem examination, paying careful attention to the state of the brain and spinal cord, I found in both instances thickening and opacity of the membranes, with adherence to each other and to the brain, showing the existence of chronic meningitis. The brain was in both cases anæmic and indurated, and in one case there was dilatation of the lateral ventricles with considerable effusion. The spinal cord was atrophied and indurated, and there was considerable fluid in the spinal canal in one of the cases, and also at the base of the brain. Upon hardening the spinal cord and making thin sections, and employing carmine staining, to demonstrate the structural relation of the cord more clearly, I found, upon microscopical examination, that there was atrophy and loss of the nerve-elements of the posterior columns, with a new formation of connective tissue. In making autopsies, where the cause of death has been owing, directly or indirectly, to the abuse of alcohol, I have found cirrhosis of the liver, fatty and waxy liver, cancer of the liver, chronic Bright's disease, cancer of the stomach, and cancer of the bladder, and, in one case, a gummy tumor of the dura mater. It is doubtless true that in many cases we shall find upon examination no pathological changes in the brain, that are demonstrable by existing knowledge and appliances; but I think we should rather doubt the quality of our resources of observation than doubt the existence of pathological changes in this most delicate, sensitive, and complex of all organs, when we have observed during life its functions to be obviously perverted, if not destroyed.

Treatment.—Having endeavored to prove that dipsomania is a physical disease—that it is, in fact, a distinct type of insanity—I pass, in conclusion, to the

consideration of the question of the care of inebriates. I am strongly opposed to inebriates being confined in insane asylums, as they are very numerous, rapidly increasing, and a troublesome class of patients, and are a disturbing element among insane patients. They need to be in an asylum adapted in construction, location, and surroundings to their special needs. Most of this class of patients do not think that they should be placed in an insane asylum, and do not adapt themselves to their position. They are constantly demanding privileges which cannot be granted, and chafe under the restraint which is imposed upon them. They do not assimilate readily and pleasantly with the other class of patients, but domineer over and ridicule them. They are full of mischief when in an insane asylum, and interfere materially with proper discipline. Of course there are exceptions, but this is, I think, the general rule.

Dipsomania is more troublesome to manage than simple insanity, and requires, I think, more perfect discipline, both moral and physical, than the latter. In the treatment of inebriates we have primarily to build up and restore shattered constitutions and broken-down nervous systems. We have a class of patients to deal with whose digestive powers are weakened, whose appetite is impaired, whose muscular system is enfeebled, and whose generative function is often decayed; the blood is impoverished and the general nutrition disordered. They are indirectly predisposed to the acquisition of nearly all diseases, as they have, by long indulgence in alcohol, lessened the power of resisting their causes. We have to deal with the results of a toxic poison, which has resulted in more or less pathological change in the brain and nervous centres. We have also to deal at times with various complications proceeding from the abuse of alcohol, such as cirrhosis of the liver, gastritis, epilepsy, various forms of dyspepsia, and, in some cases, with Bright's disease. We must place our patient under the most favorable hygienic influences, provide for him cheerful, tranquil, and pleasant surroundings, repress cerebral excitement, procure sleep for him, and we must also give him plenty of good, nourishing food and an abundance of fresh air and exercise. I believe that to this disease, as to insanity under other forms, the remarks of Sir James Coxé are equally applicable, that "purgatives, hypnotics, anodynes and tonics are useful auxiliaries; but a comfortable meal is the best of sedatives, and abundance of exercise the best of hypnotics." All remedial measures are, I think, inferior to wholesome exercise of body and mind in this disease. We must provide amusements of every kind, and encourage patients to work. We must stimulate inertia, resist every kind of perverted feeling, and check morbid impulses; and at last we may, if we exercise a wise care and discrimination, restore our patients to their homes and to society, permanently cured.

A NEW FOOD.—A society of rat-eaters has been formed at Gembloux, in Belgium. The members meet once a week, and the proceedings are wound up by a grand banquet, in which preparations of that delicious animal hold a prominent position. This society, following the example of the Hippophagic Society, wishes to destroy the prejudice attached to the flesh of these little animals.

In the furtherance of this object, a learned Belgian has been at the pains to discover that the ancient Romans formerly ate gray mice seasoned with acorns and chestnuts. Buffon relates that the inhabitants of Martinique eat mice, and are especially fond of musk-rat.

Progress of Medical Science.

CARBOLIC ACID POISONING TREATED BY THE INTRAVENOUS INJECTION OF AMMONIA.—The following case is of interest, as showing the poisonous action following a known dose of carbolic acid, and the means which were apparently successful in saving life. An anæmic woman, six weeks after confinement, was received into the Bristol Royal Infirmary, for an abscess about the hip-joint. In some way she managed to possess herself of a mixture of carbolic acid and linseed oil (1-10), and swallowed of it a measured fluid ounce, which therefore contained about fifty grains of the acid. Twelve minutes afterwards the house-surgeon saw the case; the woman was then able to understand and to reply when spoken to sharply; the skin was moist, the face dusky, the pulse weak, and the pupils slightly dilated. A stomach-pump was immediately put in use and the stomach was washed out continuously with warm water, until it exhibited no signs of the oil or smell of the acid. The bad symptoms, however, continued to increase in intensity, while the pulse became rapid, irregular, and hardly perceptible. At the end of three-quarters of an hour coma was complete, the face perfectly livid, the skin bathed in sweat, and the muscles of the soft palate and tongue so relaxed that it was necessary to have the latter organ constantly drawn out to allow of breathing. Death being apparently at hand, it was decided to inject ammonia into the veins; and accordingly two drops of the strong liquor ammonia, diluted in water, were injected into a vein of the forearm. The effects of this remedy soon showed themselves, for the radial pulse soon became perceptible, and the other symptoms slightly improved; still, the effect was transient, and accordingly, fifteen minutes later, the injection of an equal amount was again made, and again with marked benefit. After fifteen minutes a third injection was made. Within another half hour consciousness had returned. On recovery she complained of no pain except in her tongue, and improved gradually, though she suffered some days from gastric catarrh. The writer thinks this is a case illustrating the fact that where there is no direct antidote for the poison the injection of ammonia may be of great value, sustaining, as it does, the powers of life for a few hours, until the critical period has passed.—*The Lancet*, Sept. 25, 1875.

ACUTE ENDOCARDITIS IN TUBERCULOSIS.—Acute endocarditis has been described in the majority of the virulent or infectious diseases, particularly in variola, scarlatina, and measles, in malarial intoxications, puerperal fever, diphtheria and septicæmia. M. Perroud has had occasion to observe it also in tubercular phthisis, and has arrived at the following conclusions:

1. Acute tuberculosis is to be counted among the number of infectious diseases, in the course of which acute endocarditis may manifest itself.

2. Usually this endocarditis does not have time to develop itself fully, the tubercular disease carrying the patients off before the valvular lesion has attained an advanced degree. As a rule, at the autopsy, only little nodules are found, more or less pronounced, and which have already been described by authors in a certain number of the infectious diseases, and are very different from the tubercular granulations, very few examples of which have been observed.

3. When the tuberculosis has a sufficiently long duration, the endocarditis may attain a more advanced

development, and so interfere with the action of the valves, as to give rise to physical or functional cardiac signs.

4. It is then generally the vegetating form of acute endocarditis that is observed. The writer has never in these cases encountered the ulcerative form. With regard to the sclerosis of the valves, which is so common in adults after acute rheumatism and which develops slowly, he has never observed it in tuberculosis, and is of the opinion that it must be very rare in this affection.—*Lyon Medical*.—*Gaz. Méd. de Paris*, Aug. 7, 1875.

OBSTINATE INTERMITTENT FEVER CURED BY STEAM BATHS.—Dr. Finkelstein, of Jassi, in Roumania, states that intermittent fever is exceedingly prevalent in that country, and that while most cases yield to quinine in large doses, and to arsenic, obstinate cases sometimes occur which defy all ordinary treatment. He instances his own case as one of these. First attacked in 1865 with a quartan he was benefited by quinine, but had relapses whenever he stopped taking it, until he went to the mountains. He was then free from it for six years, until 1871, when he settled in Jassi. From this time until 1874 he was constantly subject to attacks—the paroxysms lasting from seven to eight hours. He took quinine and Fowler's solution, which had good temporary effects; also piperin, carbolic acid, and tincture of eucalyptus globulus, all without effect. On September 4, 1874, he had the premonitory symptoms of a chill, and it occurred to him that as the process always ended in perspiration, if he could induce free action of the skin an earlier defervescence might set in. He determined to take a steam bath at once, and before he could get his clothes off his teeth were chattering. His pulse was then 96. On entering the hot chamber its temperature was 102.2° F. He directed the heat to be increased, and when it reached 105° he began to have an agreeable feeling of warmth, and broke into a perspiration. Pulse then 100. After fifteen minutes, beginning to feel some oppression in the chest, he left the hot chamber and took a cold douche. Finding, however, that the chill had not left him entirely, he returned to the sweating room, the temperature of which had meanwhile risen to 107.6°. He remained there for twenty-three minutes longer, the temperature of the room reaching 111.2°. At this time he began to feel dizzy, and at once left the hot room, had himself well rubbed and douched, and at the end of the whole process, which lasted nearly an hour, he had no chilly feelings, and his pulse was 80, sinking to 70 after he was dressed. Six months had elapsed when he wrote, and he had had no return of the disease, and had taken no medicine. Dr. F. reports equally good success in the treatment of a similar case, in a patient of his, whom quinine and arsenic would not cure.—*Berl. klin. Woch.*, Sept. 6, 1875.

CARBOLIC ACID IN DIABETES.—At the session of the General Surgical Society of Cologne, held on February 15, 1875, Boese reported a series of observations made on a case of diabetes mellitus, which had been treated with carbolic acid. A quantitative estimate was made daily of both the sugar and urea. The patient was kept on an abundant ordinary mixed diet for sixteen days; then for fourteen days on a strict diabetic diet; and then for a further period of thirty-one days while on the same diet carbolic acid was given in the way recommended by Ebstein and Müller. For a further period of fourteen days the carbolic acid was suspended, while the same diet was continued. The patient then took the acid again until discharged. It appeared from the analyses,

that on beginning the diabetic diet the quantity of urine and of sugar diminished, and remained so while the amount of urea continued at about the same figure. On giving the carbolic acid, the amount of urine and of urea remained unchanged, but the sugar diminished by one per cent. to increase by that amount when the acid was discontinued, and diminish again when it was resumed.—*Berlin. Klin. Woch.*, Sept. 13, 1875.

STATISTICS OF VESICAL CALCULI.—Dr. Ultzmann, of Vienna, has examined eighty-three specimens of calculi, belonging to Prof. Dittel, and has grouped the interesting points regarding them as follows: He found 28 of them composed of uric acid, 10 of oxalate of lime, and 45 of phosphates. Those in the first group consisted chiefly of uric acid, with some urates. In some also there were thin layers of earthy phosphates and oxalate of lime. The nucleus was free uric acid in 21 cases, in two oxalate of lime, while in five it could not be made out owing to the small size of the fragment. In one case there were seven stones, in one six—in fact six pieces from a previous lithotripsy—in one three, in one two, and in the remaining twenty-four but one stone. The weights ranged from one ounce and six drachms to ten grains. The color of these stones was a shade of yellow, unless incrustated with the gray or white earthy phosphates. The surface was either smooth or slightly uneven.

The oxalate of lime calculi consisted mainly of this salt, with occasionally alternating layers of uric acid or phosphates. The nucleus in some instances was free uric acid; in one it was too small to be estimated. In only one case were there two stones in the bladder. The weight varied between two ounces and fifteen grains. In color they were dark brown or blackish brown. Their surfaces were markedly irregular, resembling a mulberry, even when coated with phosphates. The form was generally spherical.

In case of the phosphatic calculi they were found generally to comprise a mixture of amorphous phosphate of lime, granular carbonate of lime, and crystalline ammonio-magnesian phosphate; the general structure of the stone depending upon the preponderating ingredient. In one case where there were four stones in the bladder they consisted of crystalline phosphate of lime, with ammonio-magnesian phosphate, and were smooth, hard, dark gray, and of polygonal form. The nuclei consisted of such various substances as hair-pins, sealing-wax, pieces of rubber catheter, etc., of lengths reaching as high as four inches, and again of small coagula of blood, and of drops of oil mixed with earthy phosphates; in 7 cases of free uric acid, in 9 of phosphates, while in 21 it could not be ascertained. In one case there were twenty two small stones, in one four, in one three, in two cases there were two, and in the rest but one stone. The heaviest weighed three ounces and two drachms; the lightest five grains. The color was white, grayish, or yellowish white; the surface rough and sandy. In form they were generally long and oval.—*Wiener Med. Woch.*, Sept. 18, 1875.

TRACHEOTOMY IN CROUP AND DIPHThERIA.—Dr. George Buchanan, of Glasgow, says that (regarding membranous croup and laryngeal diphtheria as distinct diseases) there is a point in both where it is evident that recovery is hopeless and that death from suffocation is certain; and though it is difficult to say when that stage has arrived, he thinks it better to err on the safe side, and acknowledge the inefficacy of medical treatment, after a fair trial, rather than delay the operation until the strength of the child has been almost exhausted by its struggles for breath. He urges

upon all physicians, after the medical treatment has been tried and found to be unavailing, and when death seems imminent from suffocation, and not from vital depression or exhaustion, the duty of performing tracheotomy. When the suffocation, in both diseases, depends not only upon an obstruction of the trachea, but also upon an effusion of false membrane or the glutinous fluid which precedes it, into the smaller bronchial tubes, then the case is not one for operation. Owing to the restlessness and noisy breathing of the child, it may be difficult to obtain accurate information from percussion and auscultation, yet there are two valuable signs: the first is the amount and loudness of the stridor, which is always great in proportion to the patency of the small tubes and obstruction in the trachea. The second, and most valuable in his opinion, is inspection of the naked chest. When the obstruction is in the trachea, while the bronchial tubes are free, the respiratory movements are continued with exaggerated energy, but the chest will not respond to the muscular efforts. The result is that at each inspiration the flexible parts of the thoracic walls are drawn in with great force, the intercostal spaces are hollowed, and the ensiform cartilage sucked back. But when the small bronchial tubes, and perhaps the air-cells, are stopped with the viscid or membranous effusion, the muscular efforts are more feeble and the chest remains puffed out. The whole aspect is then that of a child thirsting for breath, but with the lungs already full and themselves unfit for respiration. In this latter case, he never operates; in the former, with every hope of success.

Dr. Buchanan gives the particulars of forty-six cases of tracheotomy in these affections. There were sixteen cases classed as croup, of which six were cured and ten died. Of the thirty cases classed as diphtheria, eleven recovered while nineteen died. The average is nearly the same, viz., about one child saved out of every two and two-thirds operated on; and as the operation was always done when otherwise there seemed no hope of recovery, he thinks it may be safely stated that the lives of these seventeen children were saved by tracheotomy.—*The British Medical Journal*, Sept. 4, 1875.

TRAUMATIC TETANUS SUCCESSFULLY TREATED BY CHLORAL.—Dr. Ch. P. Coryllos (Patras) reports the case of an insane man, 40 years old, who accidentally wounded himself, with a pointed stick, in the left temporal region. When C. saw him five days after the injury, the wound, which was about an inch long, was painful and the whole region swollen. He observed that the mouth did not open well, and that the head could not easily be inclined backwards. The head was also bent forwards and to the right, while the left orbicularis, levator palpebræ and depressor anguli oris, left-sterno mastoid, omo- and sterno-hyoid muscles were on the stretch. Moreover, general and increasing tetanic contractions began to show themselves. He was given a purge followed by chloral in twenty-grain doses every hour, until four had been taken. He slept well, and the next morning the cramps were less severe. The doses of chloral were increased after a week to 115 grains a day. On the twentieth day two portions of the stick were removed from the wound. During the following night he suffered from priapism and sleeplessness, tried to escape from the house, and had tetanic seizures again. Chloral was given with morphine. He was finally discharged cured at the end of five weeks, after taking in all over five and three-fourths ounces of chloral.—*Allg. Wien. Med. Zeit.*, 4, 1874.—*Rundschau*, Sept. 15, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

GEORGE F. SHRADY, A.M., M.D., Editor

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, November 13, 1875.

THE APPROACHING CENTENNIAL AT PHILADELPHIA.

ACCIDENTAL circumstances, dating back to Revolutionary periods, have now made Philadelphia a centre of Centennial attractiveness. Any other city might have had similar honors bestowed upon it, and have claimed them without a contest, had similar antecedents been part of its history; but such relations of intimate connection with the birth of the Republic fell to no other's lot. It has not, therefore, been a matter of surprise that almost all the national medical and scientific associations which are to meet in 1876—and incidentally among these the International Medical Congress—should follow in the current which for one exceptional year is setting toward that city. There has clearly been no alternative for the rest of the country but to yield the temporary and preliminary occupation of the field gracefully, and with a sense of propriety almost akin to duty, to those who, on hallowed Centennial ground, will fitly do the honors of the occasion. Having once conceded this much, we trust that the active sympathy to be tendered from every quarter towards the success of this Congressional undertaking will be manly, cordial, and fraternal. The International Medical Congress must be in spirit and purposes thoroughly national before it can become to any great extent international. In other words, it must be presented to the whole medical world as an outspoken, heartfelt, and sincere greeting from brother to near and distant brother; that the ties of medical fraternity and professional consanguinity may be strengthened and new bonds formed that shall be indissoluble, and far-reaching in all their influences for good. We are assured that our medical friends in Philadelphia are truly anxious for the unanimous co-operation of all efficient agencies towards such a desirable consummation, and that, having once arranged the preliminaries for a successful fruition of the enterprise,

of whose inception they early assumed the undivided responsibility, they aim at no local glorification, other than that which naturally attends upon the happy accomplishment of a well-elaborated work. They have only prepared the mould, but the profession at large must fashion it, and give it permanent coloring and consistence. When the Congress shall meet and map out its own line of action, we have no doubt that Philadelphia will modestly retire from any position of over-prominence she may have seemed to occupy up to that period, and will claim no other honors than such as may be voluntarily accorded her by the voice of her welcome visitors and guests.

THE "UNSUCCESSFUL" PRACTITIONER.

IN the present number we publish another letter from "Diploma," detailing the experiences of a struggling and unsuccessful practitioner. Although the picture which he draws is by no means an encouraging one for the medical man of the future, we have certainly arrived at the time when the ordinary chances of success should be viewed from a calm and matter-of-fact standpoint. His former letter has excited considerable comment, public and private, and all have agreed in the verdict that there is a "great deal of truth" in the statements given. In the discussion of any subject when fundamental truths are sought after, the more telling the facts, the sooner can conclusions be drawn. Our correspondent will be thanked for the service he has done to his side of the question, in bringing up the whole subject to the surface of fair discussion and independent opinion. It is in furtherance of such motives, and in encouragement of manly and conscientious convictions, that we give place to his lengthy communication.

THE ACADEMY OF MEDICINE AND THE MEDICAL SOCIETIES.

ON the 18th instant the New York Academy of Medicine is to hold an anniversary meeting in its new building, where it has now become quite settled, and the exercises, which will vary somewhat from the ordinary course, should insure a large attendance. Since the season of medical gatherings has opened, four of our prominent associations have changed their places of meeting to the Academy building, viz., the Physicians' Mutual Aid Association, the Society for the Relief of Widows and Orphans of Medical Men, the Neurological Society, and the Medical Journal Association. The latter has taken the third floor of the building, which it occupies with its books and journals, while its meetings are held in the parlors on the first floor.

The capacity of the rooms used for society meetings will hardly admit of large gatherings, but they are amply sufficient for the accommodation of our largest societies at the present rate of attendance.

There is yet another argument for the use, conjointly, of the Academy rooms by our principal medical societies aside from that of the community of feeling and the friendships which come from frequent association; that is, the convenience of the members. It requires a considerable degree of enthusiasm to induce a tired man to leave his comfortable easy-chair and cigar on a winter night, and sit for two hours on a hard bench in a close and uncomfortable college lecture room, to listen to a paper and discussion which he can read at his leisure and ease in his medical journal of the following week. Physicians suffer enough inconveniences from their relations with the public, without enduring self-imposed hardships; and any society which subjects its members to avoidable discomforts will find that the attendance of its members and the choice of its papers will surely diminish.

Correspondence.

GENESIS OF AN EPIDEMIC OF PUERPERAL FEVER.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR,—In your issue of Oct. 30, is a report of my remarks in the discussion of Dr. Lusk's paper, before the County Medical Society, on the "Genesis of an Epidemic of Puerperal Fever," containing two important errors, which I hasten, with your permission, to correct.

I stated that I placed the twenty-three pregnant women, who were sent from the Bellevue Lying-in Service to Charity Hospital, in pavilions built out upon the grounds which had formerly been occupied by small-pox and fever patients.

In continuation, I am reported to have said: "The night of the day they were received *one died*, and the night of the *second day the second died* (*italics mine*). Up to that time nothing had been done in the way of precautionary measures, but at once the clothing was all removed, the *hair cropped*, etc., etc. (*italics mine*).

What I really said was, that on the day of arrival of these women at the Island, one woman was confined and developed puerperal fever immediately, having her premonitory chill within three hours after delivery. On the second day another woman was confined, and she developed puerperal fever with similar rapidity.

They were both put apart from the other women in a separate pavilion, and the doctor and nurse who had been in attendance were quarantined with them.

Both patients recovered. They did *not* die, as your reporter states—a fact very important to us who treated them, and we hope a matter of considerable pleasure to the patients themselves.

Then, with regard to the prophylactic measures the remaining women were subjected to—he did *not* crop their hair. We simply washed it with the rest of their persons in a carbolic solution.

I should feel very sorry if, from the report of our successful measures in preventing a threatened outbreak of puerperal fever, whose germs were so prominently present and recognized, some one else should, in adopting this plan, deem it an essential part of our system to mutilate the patient by cropping the hair.

It certainly was a very interesting and instructive fact, that these women—who came to us saturated with

this puerperal-fever virus, as evinced by the previous history of their class in Bellevue, and corroborated by the sudden incursion of the disease upon those two who were confined within twenty-four hours of their arrival at the Island, before we had adopted any prophylactic measures toward them—were so completely disinfected by the simple measures mentioned, as to render the puerperal septus present almost innocuous; so that its presence was reduced to the minimum of effect, as shown by a slight increase of temperature and pulse rapidity for a few days.

It may be urged in contrariety to this, that the epidemic was on its decline when these women came under our observation, and therefore our success was only apparent, not real. In answer to this I might state, that we have used these prophylactic measures for the last four years in Charity Hospital Lying-in service, with the uniform result of checking outbreaks of fever whenever they threaten, and limiting them when they appear.

I believe that the contagion of puerperal fever is just as limitable as the contagion of small-pox.

I sincerely hope that this subject may again come up for discussion in our medical societies, inasmuch as there are a mass of outlying facts in the experiences of many general practitioners, who generally do not take part in discussions, which, if evolved, would throw considerable light upon some of the geneses of puerperal fever.

Many of us believe that it is one of the diseases of hospitalism, and it would be interesting and perhaps conclusive, if we could show that it is more prevalent in the experience of those who have hospital connections.

Dr. Lusk's statement, that although he was in constant attendance upon the infected in Bellevue, yet he did not have a case of puerperal fever among his private patients, is very important. It tends to prove that either the disease is not communicable through professional attendants, or that some individuals cannot, through some idiosyncrasy, be made its vehicles, the latter of which I believe.

My experience in similar epidemics has been disastrously different from Dr. Lusk's.

I have no statistics to quote, but if an opinion is worth anything that has been gleaned from conversations with many gentlemen in general practice, who are not engaged in hospital services, puerperal fever is infinitely rarer in their private practices than ours.

We know that it is very rare among the poorer tenement classes—those who live in disregard of hygienic rules, and whose lying-in chambers are the abode of want and filth.

These points, if true, are worth considering, and we can only properly approach the nature and cause of this dreaded disease, by eliciting in our societies a *fearless* discussion among members who have no hospital connections, as well as among those of us who have.

Very respectfully,

WALTER R. GILLETTE.

129 WEST TWENTY-THIRD STREET.

THE MORAL ASPECT OF SUCCESS IN PRACTICE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR.—I have read with much interest "Diploma," "Success," "M. D. V. S.," and "Successful Practitioner," in Nos. 252, 255 and 257 respectively. I sincerely think we cannot spare "Diploma" from our profession, and I will agree to be one of a thousand to "chip in" and carry him a year or two, just for the

service he has done in writing that letter, accompanying his departure from our ranks. "Success" criticises him in some respects fairly; he evidently is a better collector than "Diploma," but much his inferior in wielding the pen, and he also partially pleads for a great wrong in our profession. I refer, of course, to our so-called "Medical Schools."

"Successful Practitioner" handles those "high-toned" gentlemen rather roughly, but they have opportunities for defence. I am delighted to see this subject opened by you for discussion.

"Diploma" has told us some *truths*, and told them in an elegant and classical manner.

"Success" has told us nothing new, and "Diploma" anticipated his argument in the first ten lines of his article.

Now I wish to consider this question of our college system aside from its bearing upon the issue of success in life.

I wish to place it upon a higher plateau, for I religiously regard it as *the one* great malady for us to treat; and I appeal through you to those who love their profession as they love humanity, and who love the truth as did the martyr, to redeem the next generation of doctors, although we may reap no other benefit than the moral one of having an interest in the future. We sometimes must sow the seed, although we may never live to see the fruit. The question, then, is one of morals, and it is either our duty to sustain our present system of schools, or it is our duty to modify them, as the case demands. It is either our duty to encourage this promiscuous *sale* of diplomas, which makes our profession a *trade*, or it is our duty to stop it. We have abundant power to do so, and we are to blame for its existence in the future.

Our medical schools are a great improvement on none, and we find their pupils superior to our ancestors, who graduated from the apothecary shop, or to the Sioux Indian "Medicine Man," who is taught by tradition; *but not very much their superior.*

Doubtless there are venerable and high-toned men connected with our colleges, yet they are, beyond a doubt, also conducting institutions for their personal gain. It may, or it may not, militate against the character of a "high-toned" gentleman, but *they do* speculate most mercilessly upon about three thousand gullible youths annually, and the worst is this: the whole nation has to pay the penalty for the *ills* of this low grade of scholarship.

We annually turn out more *poisonous material* from the numberless medical schools scattered through our cities and hamlets than all the distilleries of a generation. It is easier to secure a diploma from the best medical college in the States, than to learn to make a panel door, or to lay a brown-stone front, or to put a cornice on our hall ceiling; yet we are offended if we are not regarded as a *great profession*. We advertise and invite *every one* to distinction, provided only he or she be eighteen years old, and has money enough to pay for the course of lectures, and thirty dollars for a sheepskin.

I was taught to believe that all one had to do to become a member of a great scientific body was to possess one of them, and conscientiously followed my teachings, but would not do it again, nor advise any one else to do so. I was a graduate of one of the best colleges in America, and when I left the dignified influence of President Woolsey—whose officers we never met in public without a respectful salute, and who never entered the lecture-room unless we arose and stood uncovered till he was seated—I say when, with the recollections of a dignified senior, I entered one of

the best medical colleges in New York City, and saw the iron-gray professor enter the lecture-room amid the clapping of hands and shouts such as accompany a clown into the circus ring, I never ceased to wonder; and when I gazed about I saw a list of *boys* displace my old-time associates, and felt that the "golden era" had truly been succeeded by the dark ages.

Those nervous, anemic boys instantly threw aside their cheroots and cigarettes, and pocketed their pipes, to draw forth their note-books and *scratch* for dear life, to keep even with the professor for one hour. What a vision for one entering the gateway of a great science!

Now I submit this picture of a scene which those "high-toned" gentlemen are witnessing daily at this season of the year, and submit for their consideration another picture (more than two thousand years old) of the great academy where Hippocrates and Theophrastes discoursed daily to two thousand students, of the most illustrious families of that enlightened era. Verily it is a great gift to behold the light (?) of this nineteenth century!! About one hundred ambitious physicians and surgeons of New York, and about the same number in Philadelphia, and half that in Boston, manage our colleges for their profit, and a thousand or two others in the same cities calmly look on, and are daily humiliated; hence, as I said above, "we have abundant power to stop it, and are to blame for its existence in the future." Do we need such schools for the next generation? Is the health of our armies, of our navy, and of forty millions of civilians to be *always* entrusted to such boys? Are the great unanswered questions of the science of medicine to be solved by such untaught boys? Can the fountain rise above its source of supply?

We scold because we command no respect at our State capital; we scold because we cannot *legislate* into the vulgar brain that the *regulars* are more able than the *quacks*; and we scold because we obtain no high rank in the army, neither in the navy. Please look at the studies and the discipline in the naval school at Annapolis, and of the cadet at West Point; see their training for six years, see their examinations of five hours in each department, and this all in writing, and you will excuse them if they ignore a profession which insists on a verbal and superficial examination of, say ten minutes, before each professor, and on a moral character only to qualify him for his great work. We *have no weight* in legislation because we have no organization nor unity among ourselves, and *we* have no unity because we have no common ground to unite on, and we *don't* know, *absolutely*, enough to venture an argument before a committee which will stand alone. There is *no doubt* that our profession is overcrowded, and chiefly so because our colleges open their doors to "all sorts and conditions of men" and women and boys, without any preliminary training, without *any necessary* condition, except the deposit with the clerk. The only *necessary* difference between a boy, or a girl, who *results* in a doctor and one who *results* in a shopkeeper is that of a few hundred dollars, cash or credit.

We graduate annually five M.D.'s to Germany's one. I repeat, then, that the thing we most need to treat is our own case. What we most need is fewer *boys* and more *men* in the profession, fewer professors and more teachers, and fewer teachers and more investigators, fewer colleges and more learning, fewer "successful" and more "unsuccessful practitioners."

Very respectfully,

A. M. D.

THE EXPERIENCES OF AN "UNSUCCESSFUL PRACTITIONER."

ANOTHER LETTER FROM "DIPLOMA."

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In my previous letter I endeavored to point out by realities of experience the dark points in the life of a medical man. I am not such a fool even as "Success" thinks I am, for I look on the man as a despicable coward who makes his misfortunes public for no other purpose than to attract general sympathy; neither do I blame everybody but myself for my discomfiture; neither am I envious of the success of "Success," or any one else.

Embryo medical men imbibe large draughts of sweetened buncombe pap, and are shown only the *enlour-de-rose* side of the picture during their education: the bitter disappointments which await so many, the consciousness that their best years and what little money they possessed have been spent in preparing them for a business from which, within no reasonable period of time, can the greater proportion expect a living—this is a state of the case which, for many reasons, is systematically ignored. It was my honest conviction that my personal history might save others from an evil fate, and hence the purpose of my letter.

Of course I anticipated the "sarkastik" smile of hundreds, the lesson of whose lives was contradicted by my letter (*vid.* "Success"); of course I expected to be called hard names, to be ridiculed, and held up as an awful example. This had its natural effect. I was completely done for—crushed. I may get better; I do not know. My chief concern is for you, Mr. Editor. In your kind but unfortunate endorsement of my letter you certainly knew the man of whom you were speaking, otherwise you would have kept silence. Truly it is very heinous in you to believe a gentleman on his word; truly you are justly, if severely, punished by being put between a pair of sneering quotation marks, and you—even the best of writers—will not show to advantage in quotation marks, just as a pretty woman looks badly in an ill-fitting costume.

It is distressing to read the withering rebuke administered to you for finding anything worth reading or that is not misrepresentation in my letter. You see in what your generosity has involved you. In itself my letter would have been passed by in silence, as beneath criticism, only because you were deluded into saying a good word for it, it merits notice that you may be set right. This is really worse than Brown-Séguard's treatment of Mr. Sumner. Do you feel yourself able to survive? I hope and believe you may, with the help of a vigorous constitution. As for me, as I said, the result is doubtful. What have I not done? I have maligned "the institutions which have the training of our young men, and thus give character to our profession." "Success" is not connected with any medical college, but he can't bear to have the colleges maligned; more than that—he can't bear *calmly* to have them maligned.

Again: I have said that the profession in this country is overcrowded, and proved my statement by statistics and personal experience to my own satisfaction. But then anything can so be proved, for one of my methods of proof has proved the existence of ghosts and hobgoblins, and of what use is personal experience when it proves such things as these? That I allied myself with the believers in spooks, by using personal experience, is truly a humiliating thought, and under the depressing influence of this reflection it is with

great diffidence that I venture to beg "Success" to tell me how many different things may be proved by the personal experience and bit of statistics in my previous letter. The subjunctive mood is an excellent thing in itself, and a particularly excellent thing in the hands of such a master of logic and English composition as "Success;" but he knows that he expresses an uncertainty by using this grammatical form; and if he doubts the conclusions I have drawn, will he not instruct me how to avoid my error by pointing out the true inference?

Again: though an admirer of eloquence and fully appreciative of the lofty flights even of an opponent, when he asks, "Tell me of what advantage would it be to him"—meaning the unworthy writer of this communication—"to have the standard of medical education raised, when even the ill-educated quack has more moral control over patients than he?" Yet one could wish that in this really great effort he had not sacrificed clearness to beauty. He is speaking of a time when, according to the construction he puts on my words, I was worsted by a pair of quacks. When we doctors suffered from the invasion of our town by the pair of rubbing quacks referred to in my letter, the most successful regular practitioner there was ready to admit that the *moral "cussidness"* of some of his patients made them go to have disease rubbed out of their "pores," and that all his *moral control* was inadequate to prevent this loss to his practice. More than one metropolitan physician of great reputation and large practice will acknowledge a like experience, and "Success" must be the most wonderful as well as most successful of men if his business is free from such complications.

The remarks of "Success" touching the inefficiency of legislation in medical matters are true enough, but gratuitous. The expression of a body such as the New York Medical Society, may be taken as fairly representative of the views of the most intelligent of the profession on this subject, and not only are we agreed to stop this business of asking bread of bribe-takers in the Legislature, and getting a stone for our pains, but in general the utter fatuity of all sumptuary laws is acknowledged. We have no protection against quacks, and the absurdity of the matter lies in expecting anything better. So when "Success" asks: "Who doubts the final issue?"—as if the ultimate triumph of physician over quack was a thing assured and beyond doubt—his expression must be taken as the bias of an extremely optimistic mind.

There are men, and they have their admirers, who think to settle a question of fact by grandiloquent language about faith in human progress, the advance of civilization, and various similar stock phrases. Such a style might be eminently appropriate if we lived in the millennium, or if the signs of the times showed the near advent of that period; but in sober common sense it becomes us to let future generations work out their own salvation, and to know that the consideration of any subject, such as the statics of things medical, is not to be facilitated by the cheap claptrap of high-sounding words, or by assurances that matters will be very different a hundred years hence.

Stripped of verbiage, "Success's" idea is, that no physician of education can really fail from the competition of charlatans, if said physician has any perseverance or grit. More than this, it is arguing against the progress of civilization to believe in successful ignorance; and for the reason that to argue otherwise is to argue that the course of civilization is backward, the instances of successful ignorance may go for nothing.

Against this sublime reasoning I have nothing but my poor facts. Has "Success" any idea what are the amounts returned as incomes by such frauds as Pierce, Sehenek, Helmbold, Von Eisenberg, Radway, Ayer, Jayne, and Hostetter?

Can "Success" name, name for name, an equal number of metropolitan practitioners, in highest standing, whose pecuniary success in anywise compares with that of these advertising humbugs?

Successful as "Success" has been, let him write a little pamphlet, with illustrations of various diseases, preferably of the genito-urinary organs—let him see that this choice effusion of his pen is well circulated—let him spend the cash he may have remaining in hiring a page of *Harper's Weekly* for advertising, and in the rent of a convenient office—let him do these things, and I can assure him that his previous success as a regular practitioner will seem pitiful after a few weeks' experience in his new departure.

What possible chance has the modest tin sign of the reputable physician against the detailed advertisement, the boasting assertions, the pills, potions, and cure-alls of the quack? "Success" acknowledges that "the educated physician has to compete with the ignorant and vulgar, always has had to, and probably always will." In spite of all this, "Success" is sure the educated physician will triumph. To argue with a man who talks in this way is argument thrown away. I do not expect to convince him, for belief and assertion are often self-supporting, however crazy that support may be; but, unless my statistics are erroneous, unbiased men will probably agree to the fact that the regular practitioner who is a conscientious exponent of the code of ethics in his professional life, must wait long, and often vainly, for a tithe of the substantial rewards which charlatans command. We cannot blame the community for this. It is common experience that no amount of education or intelligence will save the victim from the quack, for of all human pursuits medicine is the one which, in the absence of technical training, is least amenable to criticism from laymen. "Success," and men who think with him, forget that the very characteristics which stamp a man as a fraud and a pretender in the estimation of the regular profession, recommend him as an able physician to the layman of best judgment.

The layman knows nothing about the disfavor with which advertising, the announcement of specialties, and the patenting of appliances is regarded by the regular profession; but he knows that such a man as A. T. Stewart has accumulated a fabulous fortune, and that one of the legitimate methods of its accomplishment was by advertising that A. T. Stewart kept the best goods at lowest prices; he knows, likewise, of many men who have succeeded by applying themselves to the thorough acquirement of some branch of a particular art, and then taking every means to let people know of their special aptitude; he knows, lastly, that his own competence comes from the royalty on a patent he obtained for an improvement that greatly enhanced the value of some article in general use, which would have remained comparatively unknown, or never been manufactured, had it not been his interest to introduce his patent. In a word, our intelligent layman sees a man, a physician by profession, pursuing those well-known and reliable paths to success which, as a non-professional, he—the layman—believes to be legitimate and proper. Moreover, the advertiser does not make naked assertions without good common-sense dressing. He spends much money to hire whole pages of religious weeklies and popular illustrated papers, wherein he appeals to the understanding of his

readers whether it is not the proper thing to attack disease at its seat in the blood, and by the use of skillfully compounded extracts from the herbs, which Providence has provided and the doctor's long and arduous course of experimentation has shown to be specifics against those terrible diseases scrofula or king's evil, syphilis, and all forms of blood disease, so to cleanse, and at the same time enrich the great vital fluid that the very essence of all the foul humors is dispersed, the vigor of youth restored, and life renewed.

Such coin as this, however base its ring to us, passes current as true metal with our intelligent layman; he thinks doctors are prone to shake their heads about simple matters and to complicate cases unnecessarily, whereas, disclaim it as he may, he likes to reason about the causes of things, and is ready with an opinion on the state of the bodily fluids in a cancer subject when Virchow and Rokitansky are silent. If we remember that it was not very long ago when medical men looked no farther than the stomach for all the ailments which Broussais believed worked a constant change in that viscous, we will readily understand how a man may be a good judge, or an acute philologist, or even a sharp rag-baby politician, and yet go to the world's dispensary to have his difficult and expensive disease laid before a consulting board of physicians (?) of that famous institution. Is any one so wise as to contend that legislation is a remedy for this?

"Success" is so extremely suggestive in his remarks, that to consider all he says will spread this letter beyond all limits; but let me call attention to this:

"I believe that the law of supply and demand alone can regulate the number of men who practise medicine, and that medical colleges are just as subservient to that law as individuals. . . . Encourage them to elevate their standard for the public good, and not attempt it for private gain."

Did "Success" ever read John Stuart Mill's Political Economy? If he had, he would have learned that regulation by supply and demand is often attained after a long glut in the market; persistent, fierce overcrowding; workers attracted through deceptive appearances to produce that which will find no buyers; many contestants, drawn by a single glittering prize, which can be but the fortune of one, and must prove the ruin of many. This inexorable law is certainly at work, but in a very different way from that which "Success" imagines. Whether he believes it or not, the fact is true as an axiom, that *one-half the number of physicians in this country cannot be making a living, or anything approaching one, by their profession.* It will not do for "Success" to say he does not believe this. If he can controvert the fact, he must do so by something else than mere assertion. It is a matter of simple arithmetic. Let me again use my despised morsel of statistical fact, that "Success" says can prove anything. Is it true, or is it not, that the last census returned seventy-four thousand physicians, or about that number, for these United States? It will not affect the question to count out any of these because they follow some calling besides medicine. Many young physicians eke out a scanty subsistence in many different ways, but that fact is indirect proof of an overcrowding of the profession. Now, in all honesty and fairness, I ask "Success" how a profession which in an equable distribution of patronage gives five hundred possible patients to each doctor, can be proved to offer "excellent promises of a livelihood and more, to young men of perseverance and ability?" "Oh! but," "Success" will say, "a good many are men such as you are, that is, flounders and grumblers." Exactly;

granted. But a large proportion must be men such as "Success" is—men who, as he puts it, have taken warning, or who would take warning by my "melancholy example, not to be content with the knowledge that they have an education 'much more extensive,' etc., but by untiring energy and honest endeavor elevate themselves to places of honor and emolument," etc. Suppose that we cut the number of medical men down to thirty-seven thousand, less than one-half the present number, and suppose that this number is of material after "Success's" own heart. Here we have a picked body, with all the flounders and grumblers, such as the writer, counted out, and all the men of untiring energy, etc., such as "Success," setting out "to elevate themselves to places of honor and emolument." Suppose that each man of this picked body had his exact quota of one thousand possible patients parcelled out to him, and I respectfully submit that there would be places where, for a long time—long enough for the doctor to starve—pay patients would ungenerously refuse to sicken, localities where no profit or emolument was to be had, and districts in which the most untiring energy and perseverance could only result in decreasing the doctor's weight, whereas, if he had only been a flounderer and grumbler he might have preserved a little adipose till his friends came to help him.

The matter is so serious that I do not wish to ridicule it; but seriously, it seems to me too bad that as your correspondent "Successful Practitioner" well puts it, the general belief in such glittering pictures of the statics of the profession as those drawn by "Success" and "high-toned" professors, should flatter crowds of poor students "into spending their money and time on a profession that must eventually fail them." What sort of talk is this of "Success" when, in an equable distribution, the population is not enough to support half the present number of doctors, when the immense practice of a few widely known practitioners absorbs the quotas of many of their professional brethren, and when it is notorious that the multiplication of medical charities, to which the wealthy and great subscribe, and to which medical nabobs attach their names as Visiting and Consulting Physicians, is taking the bread out of the mouths of obscure deserving men? Dear Mr. Editor, in this as in most things, perhaps, the truth is the only thing to be respected, and as "Success" demolished me through you, may I be allowed to say to him, or others thinking as he thinks, through you, that when next they write you a letter, it will be more satisfactory if in place of beliefs which persist after reading my letter (vid. "Success's" communication), they give us some testimony to the truth of their beliefs. To "Success," as the would-be champion of the medical colleges, I will say that I too know men amongst the professors whom I believe to be "honorable and high-toned." Nevertheless, I do not retract the charge which he characterizes as "base and groundless." If "Success" could question the professors about each candidate, as he appeared on the stage to get his diploma, and ask whether the statement, "This candidate has attended two full courses of lectures," was absolutely true, the response, if conscientiously given, would be, in many cases, that so far as the professor's personal knowledge went, he could not say. On the other hand, I can positively assert that the faculty to a man possessed positive and reliable information that each candidate had paid his fees to the last dollar. The only exception might be the case of a substitute, a dummy—the *bona-fide* graduate having paid his money, received his diploma, and gone home to practise, whilst the faculty, that ap-

pearances might not suffer from this contemptuous avoidance of their barbecue, bribed an under-graduate by the present of a stage ticket, to represent the delinquent.

It is not for the rigid exaction of fees that fault is found. Professors are but men, and no one but "Success," whose contempt for the great motive power is constantly evidenced by such exalted sentiments as "encourage them (the colleges) to elevate their standard for the public good, and not attempt it for private gain," either desires that a man should, or believes that he would, accept a chair in a medical school, or hold a hospital position for such reward as the sweet consciousness of doing good alone could give. There is nothing so pitiful as the wretched underbidding of each other by starveling country medical colleges, and if city schools can flourish on large fees, by all means let them charge the highest, and derive such dignity therefrom as may be had from that fact. It is the system that is wrong. In London the most successful school, and the one which makes the most money, is that which puts the greatest number of men through the examinations of the London University and the Colleges of Physicians and Surgeons. All honor to such a competition as that. When candidates are on an equal footing, and unknown to their examiners, other things may have been important before, but the one thing important then is ability to pass the examination. Has "Success" never heard, can he not understand, that the greatest boast of the New York colleges is the great number of men they turn out as M.D.'s.

If he knows anything at all of the matter, can he affect ignorance of the fact that the supreme point of rivalry amongst the three colleges is which one shall excel the other two in this wholesale, iniquitous manufacture of doctors? Has he never heard it said of a notoriously dull student, "He is one of Prof. —'s" — mentioning the name of one of the Faculty—"men, and is sure to pass?" Has he never known the joining the private class of a professor to save a man considered very sure to fail? Are there not men given diplomas, licensed to undertake obstetrical operations, practise surgery, and who are liable to be called on as experts in coroners' cases, who, for aught those who conferred all these grave powers upon them know to the contrary, never witnessed a case of natural labor, never opened an abscess, and never performed an autopsy? Grant this is an extreme case, the point is that with the existing system it is possible, and I challenge denial. Finally, is it not an assumption too outrageous to suppose that, of one hundred and fifty men whose manners and conversation prove that the majority are strangers to any but the most rudimentary general training, all, with the exception of a paltry dozen or two, can be found fit, at the end of the prescribed two years, to exercise the varied and trying responsibilities of the physician?

There could be but one result to all this, and that, Mr. Editor, you point out well in your editorial of the 16th October.

"Not only in the metropolitan centres, but in the most remote hamlet this competition is active, for nowhere are there any places vacant which enable any one practitioner to claim the unquestioned monopoly of the practice of any community."

If anything, you have understated the existing competition. Ask old-established medical men to recommend an opening to a young doctor, and see how few the responses. Yet the colleges go on each year turning out more men, more men, and the cry is still they come, at the rate of thirty-five hundred yearly. Per-

haps even "Success" will acknowledge this is a little too fast for the population. The remedy lies beyond our reach. We have made our bed and must lie in it. When the time comes, as it doubtless will at this rate, and after the delusion about there being plenty of room in this "great and growing country for all the doctors that can be turned out" is dispelled—when the time comes that each household hires its doctor as it does its servant—then, perhaps, things will be organized on a new basis, and we will have a copy of the extreme German plan,—gymnasium, university, five years' study, and thoroughness.

One word more to "Success."

Since writing you my previous letter, and before my new plans were complete, I was advised to try a locality where, from the retirement of a physician in large practice, doctors were not very thickly planted.

I have not changed any that I know, and if I grumbled and floundered before, I grumble and flounder still; but having now somebody else's and my own quota of patients I find grumbling and floundering pecuniarily successful.

Neither "Success" nor success has yet turned my head, and I can yet sympathize with a man who is so unfortunate as to occupy my previous box, without charging his misfortune to grumbling and floundering. Please pardon this selfish detail. It is introduced to show "Success" how—strangest of anomalies—g. and f. may be attended in one place with disaster, in another be made to pay.

DIPLOMA.

INJECTION OF STRYCHNINE INTO THE BLADDER FOR PARALYSIS OF THAT VISCUS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR MR. EDITOR:—It is, perhaps, not often that you are troubled with communications or reports of cases from America's antipode; but as to me at least there are some points of interest in the history of the following case, I take the liberty of reporting it, in the hope that, if you consider it worthy of publication, it may be of some interest to my professional brethren at home.

Mrs. B., æt. 33, the wife of an English missionary, was taken in labor with primipara, about midnight, August 15, 1875. At half-past one o'clock A.M. I was called, and found the os uteri somewhat dilated, parts moist and cool, head presenting, and all things normal with the exception of a very narrow pelvis, but as the head of the child was not large I hoped that nature might be adequate to the situation. The first stage of the labor was normal, although rather slow, and by six o'clock A.M. the head of the child was in the lower strait, and there, notwithstanding very severe pains, it remained until ten A.M., when her strength seemed suddenly to fail, and she became very nervous, crying and laughing alternately, with a good deal of muscular twitching. The pain was now constant, but appeared to have not the least expulsive force; consequently about half-past ten o'clock A.M. I administered chloroform, applied the forceps, and by using a great amount of force, succeeded in delivering her of a living child, weighing about six and a half pounds, which—I may say in passing—is at this writing alive and well. The placenta came away in about twenty minutes, by aid of gentle traction, and there was not much flooding. And now comes what, to my mind, is the interesting and unusual part of the history. About six hours after delivery Mr. B. came to me and said that Mrs. B. had a great desire to urinate but

without the ability to do so. I introduced the catheter and drew off somewhat over a pint of normal urine, telling her that she would probably have no further trouble in passing her water; but in this I was, as the sequel will show, much mistaken, for from that time until Sept. 4th—a period of twenty days—I was obliged to use the catheter twice daily, she continuing to have, despite all that I could do for her, not the least power over the bladder, and remaining unable to pass even a drop of water. At this time it occurred to me—from the success which I have had from its subcutaneous injection in case of paralysis of the optic nerve (a disease very common in China)—to try injections of sulph. of strychnia.

I accordingly prepared a watery solution of the strength of one gr. to two ozs., of which I injected into the bladder one drachm three times a day in about one-half ounce of tepid water. And here the history of the case nearly ends; for after the administration of the third injection (the strychnia having been in use as an injection, from first to last, about fourteen hours), a copious voluntary flow of urine came on, and Mrs. B. has since been in possession of all her natural functions.

Query.—Did pressure *produce* and strychnia cure the paralysis? I leave my professional brethren to answer, simply submitting the case, with the hope that others may be stimulated to test more extensively the value of strychnia as a subcutaneous and local application in cases of a kindred nature. I may mention that Mrs. B. had taken strychnia in full doses *per oram* previous to the use of the injections.

If agreeable to you, you may expect to hear from me again ere long in regard to China and its diseases, the working of our mission hospitals, etc., etc.

Fraternally yours,

W. E. TARBELL, M.D.,

Am. Meth. Epis. Mission.

CENTRAL CHINA MISSION OF THE METHODIST
EPISCOPAL CHURCH, KIUCHANG, Sept. 12, 1875.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Oct. 31st, 1875, to Nov. 6th, 1875.

EDWARDS, S. A., Surgeon.—Granted leave of absence for six months, on surgeon's certificate of disability. S. O. 223, A. G. O., Nov. 4, 1875.

MONROE, F. LE B., Assistant Surgeon.—Granted leave of absence to Dec. 31, 1875, and his resignation accepted by the President, to take effect Dec. 31, 1875. S. O. 222, A. G. O., Nov. 2, 1875.

CLEARY, P. J. A., Assistant Surgeon.—Granted leave of absence for 20 days. S. O. 207, Department of the Missouri, Oct. 27, 1875.

NAVY.

November 7.

COONAN, JOHN N., Acting Assistant Surgeon.—Detached from duty at the Navy Yard, at Pensacola, and placed on waiting orders.

A HOMOEOPATHIC HOSPITAL IN BROOKLYN.—The Brooklyn *Argus* publishes a petition to the Board of Charities of the County of Kings, on behalf of the Trustees of the Homeopathic Hospital, asking for the use of the vacant Nursery buildings, at Flatbush.

Medical Items and News.

NEW JOURNALS.—*The American Journal of Microscopy and Popular Science* is a new periodical which is to appear monthly under the auspices of the Handicraft Publication Co., of 37 Park Row. It comprises eight pages octavo, and is furnished to subscribers for fifty cents a year.—*The West Virginia Medical Student* is another monthly of thirty-six pages, edited by James E. Reeves, M.D., who is also the proprietor. It is published at Wheeling, and aims to advance the local medical interests of the State. Its first number is a very creditable one in every respect, although only one of the four leading articles is by a Western Virginian; one being from a New Yorker, one by a Philadelphian, and the other by a Baltimore physician. We hope its editor may be more successful in future numbers in securing home productions if he intends that the *raison d'être* of his journal shall be the representation of the local and State profession.

THE INDIANA JOURNAL OF MEDICINE, edited by Thad. M. Stevens, M.D., has been consolidated with the *Cincinnati Lancet and Observer*, after an existence of five and a half years, owing to the ill-health of its editor.

THE JOURNAL OF ANATOMY AND PHYSIOLOGY has added to its staff the Prælector of Physiology in Cambridge and the Professor of the Institutes of Medicine in Edinburgh, so that it is now under the control of Professors Humphrey, Turner, Foster, and Rutherford.

DR. JAHR, the disciple of Hahnemann, has recently died at the age of seventy-five years, at Brussels, where he had established himself, having been forced to leave Paris at the time of the Franco-German war.

A NEW SCHOOL OF ANTHROPOLOGY has been founded in Paris. Courses of lectures on the various branches of science have been arranged, and are to be delivered at the École Pratique, by MM. Broca, Dally, Mortillet, Hovelacque, Topinard, and Bertillon.

PROFESSOR MORITZ SCHIFF, of Florence, has been awarded a prize of twenty thousand francs by the Academy of Medicine of Turin, for his work on the physiology and pathology of the nervous system.

THE JOURNAL OF PSYCHOLOGICAL MEDICINE AND MEDICAL JURISPRUDENCE is to be abbreviated in title to *The American Psychological Journal*, and the Medico-Legal Department is to be added to *The Sanitarian*, after January 1st.

AN EAST INDIAN SURGEON, Ram Sundar Gose, is said to have performed lithotomy five hundred times, inaugurated charitable dispensaries in wild and remote districts, organized four hospitals, besides vaccinating one hundred and sixty-three thousand in two years.

THE ENGLISH MEDICAL SCHOOLS.—According to *The British Medical Journal* of October 16th, the registration of students at the Royal College of Surgeons had reached the gross number of 1,540, St. Bartholomew's being at the head of the list.

IOWA STATE MEDICAL DIRECTORY.—Dr. Charles A. Lathrop, of Lyons, Iowa, is engaged in making a medical directory of the physicians of his State.

DR. JUNKEN, the Senior Professor of the Faculty of Medicine in the University of Berlin, died on September 8th, at the age of eighty-two years.

THE COMPARATIVE INCREASE OF MEDICAL STUDENTS IN ENGLAND.—*The British Medical Journal* gives the following table of the comparative increase of medical students registered at the Royal College of Surgeons during the past decade:

In 1865	the number of students registered was	1,013
" 1866	" " "	1,027
" 1867	" " "	1,125
" 1868	" " "	1,194
" 1869	" " "	1,241
" 1870	" " "	1,298
" 1871	" " "	1,475
" 1872	" " "	1,496
" 1873	" " "	1,608
" 1874	" " "	1,745
" 1875	" " "	1,754

CURIOUS BRAIN LESIONS.—*The St. Louis Clinical Record* contains a remarkable case of brain lesion. A man named Waters, living near Leavenworth, Kansas, died from morphia a short time ago, and as it was known that he had had a habit of running wires, and even nails through his own skull during his former residence in the penitentiary, a careful autopsy was performed. Two openings were found in the skull, one, which the prisoner was known to have made with a brad-awl, near the inferior posterior angle of the right parietal, and another near the superior posterior angle of the same bone. A wire was found in the brain. It had been introduced through the upper opening, and just missing the superior longitudinal sinus, had pierced to the base of the brain, a little in front of the fissure of Sylvius. It is stated that the corpus striatum was not wounded. A nail, one and three-fourth inches in length, was found lying beside the wire. Although wires had been removed during life from the lower aperture, no trace of their course was discovered. Though the patient had shown a suicidal tendency he did not appear insane, except for this habit, and could do his work with correctness and understanding.

M. PAUL BERT has received the decennial prize of the French Institute, amounting to twenty thousand francs, for his work on the effects of barometric pressure.

M. FRANÇOIS MARBEAU, the originator of *crèches* or nurseries where working women can leave their infants to be cared for during the day, is announced to be lately deceased.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

[THE MEDICAL RECORD is published every Saturday. Notices of meetings, lectures, operations, etc., intended for publication in this bulletin should be received at the office, 27 Great Jones Street, one week previous, to insure their appearance.]

Monday, Nov. 15.—N. Y. Academy of Medicine, Section of Obstet. and Dis. of Wom. and Chil., at No. 12 W. 31st St. N. Y. Soc. of Neurology and Electrology.

Tuesday, Nov. 16.—N. Y. Obstetrical Soc., at the residence of Dr. John E. Blake, No. 69 W. 19th St. Cases to be presented by Drs. Thomas, Emmet and Peaslee. Med. Soc. of the County of Kings.

Thursday, Nov. 18.—N. Y. Academy of Medicine, at No. 12 W. 31st St. Anniversary Meeting, Address by E. Darwin Hudson, Jr., M.D., on "Doctors, Hygiene, and Therapeutics."

Friday, Nov. 19.—Medical Library and Journal Association, at No. 12 W. 31st St.

Original Communications.

REPORT OF
THREE CASES OF TRUE LEPROSY.

By W. JEROME DONOR, M.D.

ELEPHANTIASIS GRÆCORUM is common enough in many parts of the world, but cases occurring, as those here recorded, in a non-leprous part of the United States, without assignable cause, appear to be worthy of notice. Fortunately, leprosy, as a rule, keeps to a limited locality for a long time.

In the Arcadian village of Tracadie, near the mouth of the Miramichi River, Canada, there have been lepers, I am told, for eighty years or more, and the local government supports a hospital for their benefit. The people attribute its origin to two lepers brought by a French vessel on her return from Smyrna, and from one or the other of these men every leper is supposed to have descended. It is not there regarded as contagious, but as simply hereditary. They do not dread the affection, but work together, and marry among themselves. They say that the taint generally manifests itself every alternate generation, and in this way has become permanent in the locality; while the general poverty and rather uncleanly habits of the French population favor its propagation. It usually shows itself at first by a few or more spots, most frequently on the breast, then the face becomes swollen; there is much pain, languor, and drowsiness; the fingers become stiffened, crooked, and weak; the neck swells, the legs look dropsical, the nails fall off; at last the throat and lungs are attacked, and the sufferer dies in a loathsome condition. Its duration varies, according to strength of constitution, from five to twenty-five years.

Lepor No. 1 of the report was seen by many prominent members of the profession, and created much interest. The accompanying cuts are from a photograph at near full development of the attack, and are perhaps as fair representations as can be expected from a photograph. The scalp-tubercles, for example, are not shown.

Lepor No. 2 was first diagnosed as such by Dr. Brown-Séquard several years ago, who called particular attention to the numbness of the finger-ends and elbows.

Whether lepor No. 3 brought his disease with him from Germany or contracted it here, is not clear.

CASE I.—David B., aged 48, machinist, born in England, came to the Demilt Dispensary, April 14, 1871.

His antecedents were, born in England, and none of them ever had leprosy. The patient is a tolerably robust well-built man; has lived in New York and New Jersey for the past 38 years; has never had syphilis, or any serious illness, except an attack of bilious remittent fever while living in Jersey several years ago; and his diet has been usually of the ordinary mixed character.

Present Attack.—Three weeks ago he took a dose of "senna and salts," and the next day, while taking a long walk, got wet. The following morning he resumed his labor in the machine shop, but soon felt a severe pain in the right metacarpo-phalangeal joint, which at the same time swelled so rapidly that he called the attention of the foreman to it. Swelling of the corresponding joints of the third and fourth

fingers, with slighter pain, quickly followed; and by 9 o'clock A.M. the hand and wrist had become so swollen that he left off work. After he got home the face began to swell, so that in two days his eyes were almost closed. Four days after this, the middle finger of the left hand became swollen and somewhat painful; the neck began to swell, and two or three tubercles were noticed in the tumid back of the right hand.

Present Condition.—Face enormously swollen, with a marked leonine expression. The swellings are most prominent on the forehead; above and below the orbits; the cheeks; the chin, especially at the angles; sides of the bridge of the nose; and the ears are thickened. The neck is enlarged by thick soft ridges, with the natural lines deepened into furrows. These swellings are not painful; are smooth, soft, elastic, and of a pale red (except the ears and neck, which are of a dusky red; and backs of the hands, which are œdematous and not discolored.) The skin of the neck is rough from a thickened cuticle. A tubercle, the size of a pea, freely movable, is observed in the midst of the soft swelling under the left eye. There are also several in the back of the right hand. The skin of the wrists is of a pale red, and slightly swollen, with the cuticle thickened into flat semi-transparent eminences. The urine shows only an excess of urates. The patient's general strength is not much impaired, though his hands are weak, the right one being nearly powerless. Pulse 80, tongue furred, skin dry, bowels constipated, and the temperature, as kindly taken by Prof. Wm. H. Draper, 99.8°. The patient's chief complaint is the almost constant pain in the right middle finger.

May 5.—Swelling around the eyes more prominent, sees only through a narrow fissure; the tubercle under the left eye now as large as a cherry. Skin of the chest in front, swollen, of a pale red, with cuticle thickened into flat eminences, giving a hob-nailed appearance; posteriorly, a similar condition, though not discolored. The backs of the hands pit deeply on pressure; fingers thick and standing apart; appetite rather excessive.

May 8.—Eyes partly open; a hard tubercle in the right palm; the wrist eruption extending upwards. The chest eruption downwards; neck thickened into massive folds like a "turkey's wattles," with the furrows deepened into sulci; hands a little less swollen; inner surface of the cheeks thickened; a tubercle the size of a pea on the side of the tongue.

The patient states that his sense of smell, which had been absent for more than a year, returned five days ago, and that he now smells as well as ever. He walks a good deal, appetite ravenous, tongue moist and furred, pulse 70, temperature in axilla 98°.

May 10th.—Hands less swollen, and more pliable; folds of the neck more prominent, firmer, leathery-like, and of a darker color. Wrist eruption now half way to the elbow; trunk eruption extends to the umbilicus in front, and to the lumbar region behind.

May 12th.—Complains of a pricking and tingling at the ends of the fingers, and states that during the past night they were so painful that he walked the floor, and was feverish. Right hand red and more swollen; thick folds on front and sides of the abdomen, similar to those of the neck, though softer. A nodule as large as a walnut has appeared at the right elbow. The tubercle on the side of the tongue is ulcerated.

May 15.—Face and hands somewhat diminished, paler, and his eyes are more open. All the swellings, which until recently were soft and elastic (excepting backs of the hands, which were œdematous), have be-

come firm; the subcutaneous nodules and surrounding soft swellings appear to have run together in rubber-like masses. The forehead prominences are exaggerated; complains of soreness in the abdominal furrows; the scalp, which is bald, is dotted with smooth subcutaneous tubercles. Backs of the hands slightly anæsthetic, most marked in the right; slight anæsthesia of face and scalp, most marked on the right side. Trunk eruption extends to the hypogastric region in front, and to the sacral behind; still complains of pain in the right middle finger, and states that if he takes an alcoholic stimulant a painful tingling comes on in the ends of the fingers, and that he does not sleep well the following night. The hands are a little stronger.

May 19.—Face and hands redder and more swollen, which he thinks is due to being in the sun more than usual during the day. Some pain in the finger ends; appetite almost insatiable.

June 5.—Marked anæsthesia along the right middle finger; hands diminished in size and increased in strength; several fresh tubercles, the size of a small pea, together with others the size of a hemp-seed, are scattered over the hands. Complains of numbness and tingling at the finger-ends, and a pruriginous eruption on shoulders and chest.

June 8.—Has rheumatic pains in the knees; swelling of the hands nearly gone, though many of the tubercles remain; neck smaller, grip stronger, pulse 78, temperature 99°.

June 12.—All the swellings have diminished; circumference of the neck two and a half inches less than it was four days ago. Sweating occurred yesterday for the first time, and was forced with difficulty by a Turkish bath; last night perspiration followed spontaneously.

June 23.—Face and neck rather more swollen; grip of left hand tolerably firm. A large, soft, elastic tumor has suddenly appeared under and upon the lower margin of the left scapula, with a fluctuating feel, freely movable, oval-shaped, seven inches by five. The patient had three vapor-baths during the last ten days, but, feeling ill after the last one, discontinued them. Copious diaphoresis was effected.

July 22.—Lost sight of the patient since the above date, and during the interval some one gave him arsenic in large doses, which made him so much worse that he stopped the drug of his own accord. He complains of a troublesome dry cough; epiglottis, fauces, and palate somewhat thickened, though his voice is but slightly altered. The hobnail-like eruption has extended to the inner surface of the thighs on a red and thickened skin. Marked anæsthesia of the right middle finger; less marked in the other fingers. The body generally is hyperæsthetic; feels rather weak; complains of soreness of neck and abdomen. The scapular tumor is smaller, and gives a jerking sensation when the shoulder is rotated. A similar though smaller tumor has appeared at the lower angle of the right scapula.

Aug. 5.—Swellings much reduced; many of the tubercles have disappeared, and others are shrunken.

Aug. 18.—Eruption on all parts disappearing; hands and wrists not swollen, a few tubercles only remaining upon them.

Aug. 23.—Feels well; no pain; appetite moderate; has gained five pounds.

Sept. 4.—Considerable swelling around the eyes yesterday and to-day. Left hand apparently as strong as ever.

Sept. 25.—The scapular tumors and all the prominent swellings have disappeared, likewise the scalp tuber-

cles; cuticle in places desquamating; forehead, cheeks, chin, and inside of the thighs have still a thickened feel. There is no discoloration except in the marks of the previous furrows. The grip of the right hand is tolerably firm, and he expects to resume work in a day or two.

Treatment.—Cathartics were frequently given to meet the constipation, which was troublesome throughout. Iodide of potassium, Fowler's solution, and the mineral acids were administered successively for a time, without apparent benefit; the arsenic speedily made matters worse. Vapor-baths, as suggested by Prof. Frank Hamilton, helped him for a time, but finally became too weakening. During the last few weeks of his illness quinine was given, at first gr. xx. daily for a fortnight; then gr. xv. a day for about three weeks longer, when he was put upon the liq. strychnia ℞. three times a day.

The case is most remarkable for its acuteness. The lesions had not the usual brownish or bronzed color, the only approach to it being that of the ears and neck. There was no abrasion except the ulcerated tubercle on the side of the tongue; no scaly patches, and no brown stains after subsidence of the eruption.

It may be noticed that there was decided affection of the mucous membrane of the tongue, cheeks, fauces, etc., which, according to Dr. Living in his excellent book on leprosy, occurs only when the disease has lasted for years. There was no eruption or any signs of the disease below the upper parts of the thighs.

There was remarkable tolerance of the quinine, as none of the peculiar head symptoms were manifested, and the more rapid improvement during its use seems more than coincident. Still a doubt remains whether his recovery was not the natural decline of the attack. Should occasion again offer I should have more confidence in quinine than in anything else that I know of. We have unfortunately lost all trace of the patient since the last date.

CASE II.—J. C. II., aged 63, an accountant, was born in New York State, as were also his ancestors for five generations back; is the father of four children, all living; has never had any illness except two or three slight attacks of erysipelas in 1833-4; has always lived comfortably; and knew of no disease similar to his own among his relatives.

The first attack occurred eight or nine years ago, when a brownish-red eruption extended over the lower part of the abdomen, the serotum, and inner surface of the thighs. The parts were tender, and crusts formed which were renewed every two or three days. This eruption remained troublesome for five or six weeks, leaving a brown discoloration for more than a year. Since that time small dry patches would occasionally appear on the inner surface of the thighs; the nose became of a dusky red, not much thickened, but troublesome from the formation of scales and fissures within. A little later small dry brown scaly patches appeared in the bearded portions of the face. A numbness was noticed at the elbows, the ends and radial sides of the thumbs and index fingers, and corresponding portions of great toes. He complained of no constitutional disturbance except sleeplessness. Patient states that he has not been free from a trace of the disease since the above attack; that of the nose, with numbness of thumb and index finger-ends, having been more or less constant.

In the summer of 1872 the face eruption became aggravated, and in the following December, pain, feverishness, and sleeplessness confined him to his house. The cheeks, chin, and upper lip became thickened, with brown, scaly, fissured patches; itching and ten-

der. Soon the eruption spread over the lower part of the abdomen, front and inner surface of the thighs, the legs and ankles; the latter became swollen and oedematous. Next upon the arms from shoulders to backs of the hands, preceded by a hot feeling in the hands. Skin generally hyperæsthetic, pulse varied from 80 to 88. The scalp became covered with a thick layer of silvery scales, with here and there red points which exuded slightly upon pressure. After a few weeks patient got more restless, worried, and complained of a benumbed skin generally; most marked in the scalp; face oedematous, with somewhat of the morose aspect; eyes having a dark and rotund appearance. The patches on the cheeks, lips, chin, and legs gave considerable suffering from the formation of crusts and exuding fissures.

About eight weeks after the onset of the attack, the eruption began to subside; the crusts were replaced by branny scales, the fissures healed, desquamation of cuticle followed, and in two weeks more the patient resumed his occupation, feeling tolerably well. Up to the present date, September, 1875, he has had but little inconvenience, though patches go and come; one or more nearly always present on the chin, lips, or cheeks. A fresh light-brown patch, nearly smooth, half the size of an adult hand, exists at the epigastrium; a smaller one at the top of the forehead, and one in the left umbilical region. The old numbness of the thumbs, fingers, and great toes continues in a less degree; that of the scalp continued till three months ago. He complains of having occasionally a slight numbness in the thighs and legs. The brown stains continued distinct upon the legs eighteen months after the severe attack, and at the present date all have disappeared; even the nose is but slightly affected.

About a dozen bright-red nevus-like elevations are scattered over the trunk, which have been coming and going for two years.

As to treatment, internal remedies seemed to avail but little; quinine was not tried as thoroughly as I could have wished, the patient being somewhat prejudiced against it. The only treatment which he willingly persevered in, was warm baths daily; and frequent applications of oil or simple cerate, which certainly afforded him much relief.

CASE III. may be mentioned, though, from the incomplete history, the limited extent of the disease, and the short time under our observation, it will be perhaps of but little interest. David C—, a healthy looking German, came to the Demilt Dispensary, April 23, 1873, with thick, stiff, brownish-red ears; backs of hands slightly swollen, and the fingers somewhat thickened. He complained of no numbness anywhere. There was slight anaesthesia of backs of the hands.

This condition the patient stated came on about three months previous, remaining much the same ever since. He also stated that he was not ill at any time; that he never had an eruption before, nor upon any other parts than those mentioned; and that he came to this country about a year from the above date.

The patient suffered no inconvenience from his malady, having applied mostly on account of the disfigurement; and as treatment availed him nothing, he did not return after his second visit to the Dispensary. No change occurred in his condition during his short period of two weeks under our observation.

73 WEST 36TH ST., NEW YORK.

THE PHYSIOLOGICAL AND THERAPEUTICAL RELATIONS OF ELECTRICITY TO THE NERVOUS SYSTEM.

(Being a portion of a paper read before the American Neurological Association.)

By A. D. ROCKWELL, M.D.,

ELECTRO-THERAPIST TO THE N. Y. STATE WOMAN'S HOSPITAL.

WHILE the various methods of electrization have each their separate history, and must be regarded as entirely distinct processes, it is not to be supposed that in their therapeutical application they do not stand in near relation to each other. Very seldom in persistent and severe disease—that is in any measure amenable to electrical treatment—is it possible to rely on any one method, and at the same time derive the maximum of benefit that electricity can afford.

Localized faradization and galvanization, general faradization and central galvanization are constantly supplementing and replacing each other, in their relation to pathological conditions, and he alone will reap the reward of full success in this department who has a clear appreciation of the physiological relations of each method and an experimental knowledge of their uses.

Localized electrization necessitates, of course, an accurate anatomical knowledge. The motor nerve points must be thoroughly studied; the relative reaction of nerves, muscles, in health and disease, to both currents must be clearly appreciated; the polar influence of electricity, as distinguished from that of current direction, must be understood; in short, all those physiological changes that result from localized applications should be fully investigated.

Central galvanization demands a far greater familiarity with the physics of the constant current, and with both functional and structural derangements of the central nervous system, than is possessed by many who essay its use. If there is any one therapeutical process in the whole range of practical medicine that more than another defeats its own legitimate ends through careless and ill-directed or ignorant applications, it is this. As a matter of experiment, we submit a person in robust health, and with no marked nervous susceptibility, to central galvanization. If the current is gradually increased, and as gradually decreased, no unpleasant sensations are perceived, although ten, fifteen, or even twenty ordinary cells may be included in the circuit. The metallic taste is decided, the head experiences a sensation of fulness, and if the experiment be prolonged or the electrodes small, itching and heat will be experienced at either pole, and on the head, the seat of the anode, a slight pain of a dull, aching character may possibly be felt. A second person of increased nervous susceptibility will experience an exaggeration of all these phenomena, and subsequently may suffer from severe headache. Because of the symmetrical influence which the galvanic current by the method of central galvanization exerts on the brain, little if any dizziness is perceived, by even the most sensitive patients; if, however, the current be passed transversely through the head, the so-called falsification of the muscular sense that results through an unsymmetrical stimulation is the occasion of immediate and intense vertigo.

In thus transversely galvanizing the brain, the hemispheres are differently affected, and the result is a disturbance of the equilibrium. This dizziness, as a rule, passes off immediately on the removal of the electrodes, in healthful conditions, and is attended by no harmful results. In certain pathological conditions,

DR. KUNDRAT, lately an assistant to Professor Rokitanzky, has been appointed Professor of Pathological Anatomy in the University of Graz.

however, and signally so when such conditions are associated with those peculiarly impressible nervous organizations that are so familiar, transverse galvanization of the brain is a highly culpable procedure. Let it be clearly understood then, that, as a rule, transverse galvanization of the brain should be avoided. If it were necessary, I might cite not a few suggestive cases, and not alone from my own experience, illustrative of the importance of this law; but it will perhaps suffice if I simply indicate a few guiding propositions. In the first place, there is a certain class of patients, that I just alluded to as being peculiarly impressible, who will in no degree be benefited by this form of application; on the contrary, if there is mental or physical derangement from any cause, such applications inevitably aggravate the existing disturbance. I would that I might specifically designate this class to the tyro. In most instances there is no outward indication of any such susceptibility, and very frequently the most careful examination will fail to elicit a suspicion of any unusual relation of the nervous system to electrical stimulation.

It is only when you come to subject them to the test of actual treatment that idiosyncrasies are manifested that would not be distinctly revealed by any other method.

In two exceptional cases, for example, a current of comparatively feeble tension caused an astonishing aggravation of functions of all the nerves of special sense.

If the statements of the patients may be trusted, the cerebral commotion during the applications was excessive.

Sight, smell, taste, and hearing were all perverted and exalted, and that these evidences of excitation were not the result of fancy, I thoroughly satisfied myself by unerring tests. In these cases, as in a number of others that enter as factors into the experience that guides these observations, the after-effects were only less unpleasant than the primary, and were disagreeably persistent. Now observe the effects of applications by the method of central galvanization in the same patients. The same tension of current caused a decided metallic taste (but no vertigo and no ringing in the ears), with a slight feeling of fulness about the head, and a persistence in this form of treatment resulted in grateful relief. In consideration, therefore, of these facts, we should ever be watchful for these susceptible cases; and to avoid errors of judgment that might prove unfortunate, we should not presume even on the most extended experience, but should in the beginning pursue a tentative course. In the second place, we have in cerebral effusion and softening, and more especially in cerebral congestion, conditions that call for care, in any method of galvanizing the nerve-centres. In old apoplectic cases transverse galvanization of the head has often been used with no unpleasant results, but this certainly is no reason why it should be thus used. There can be no doubt that it might in many instances prove exceedingly hazardous, and I have seen unmistakable evidence of the ill effects (in producing dizziness and nausea) of an injudicious application of localized faradization in the neighborhood of the base of the brain. It is in the consideration of the symptoms of cerebral congestion, however, that we see most clearly the importance of rightly selecting our methods of electrical treatment. To give any direction to the current, excepting a longitudinal one, by which I mean from the summit of the head downward, or from forehead to occiput, is, I believe, not only unphysiological, but, as well, contrary to the teachings of all extended and carefully guided experience.

In this connection, and especially with reference to central galvanization, an exceedingly important practical point arises concerning *polar influence* and *current direction*.

Is the position of the poles, or the direction of the current, the more important factor in the production of therapeutical and purely physiological effects?

It must be acknowledged that the contraction laws of Pflüger render it quite possible that in the electrical stimulation of a given nerve-piece, the polar influence has more to do with the resultant physiological effects than the direction of the current.

These laws are thus formulated: "The nerve is excited by the appearance of anelectrotonos and by the disappearance of catelectrotonos, but not by the appearance of catelectrotonos and the disappearance of anelectrotonos." More specifically, Pflüger's laws may be thus stated:

First. "The mildest currents applied to the nerve cause contraction only on closing the circuit independently of direction.

Second. "Currents of medium strength cause contraction both at closing and opening in both directions.

Third. "Strong descending currents cause contraction only at closing the circuit, while strong ascending currents cause it only at opening."

Although it is impossible to illustrate these laws by clinical experiments on patients, they can be readily verified on the fresh nerve of an animal. In experimenting on one's self or upon others, the strongest current that can be well borne produces the effect only that follows the application of a very mild current directly to the nerve; viz., contractions only on closing the circuit independently of direction.

The French school, and notably Legros and Onimus, deny the efficacy of polar influence in exciting physiological phenomena, ascribing them chiefly to current direction. They ascribe anelectrotonic effects to electrolytic action, and to the induction of currents of polarization. In support of Pflüger's laws, on which are based the theory of polar action, I refer to some interesting experiments by Dr. Mason, published under the title of "The Polar Action of Electricity in Physiology," in the *New York Medical Journal* of December, 1874.

Now in central galvanization proper we generally understand that the anode is above and the cathode below, and according to the theory that polar influence is the chief cause of physiological phenomena, this position of the poles in central galvanization would seem, on physiological grounds alone, to be chiefly indicated for the relief of symptoms of central origin. The teachings of experience at all events strongly confirm its propriety.

It is very certain that in many conditions, and especially in neuralgia and spinal irritation, therapeutic effects vary according to the position of the poles.

In central galvanization also, few facts are better established in my mind than that certain conditions, such as cerebral congestion and forms of hysteria, may be injured rather than benefited by what are termed ascending currents, but whether the ill effects are due to polar action or current direction, I am not prepared to say.

When we come to the consideration of general faradization, we enter upon one of the most, if not the most, important departments of electro-therapeutics.

General faradization is a term that has become somewhat familiar to the professional ear since we first introduced it eight years ago, but its rationale, its *modus operandi*, and the necessity of thoroughness in the details of its application, are illy appreciated.

When we reassert the idea enunciated at that time, that electricity is not only a stimulant but a tonic of great power, we do not refer to electricity *per se*, if the idea may be thus expressed, but to electricity used after the method of general faradization, which in its most thorough form demands that the whole body, nerves, muscles, and all organs of special function, be, so far as possible, brought under the influence of the current.

When, therefore, persons declare that they have tried electricity on many occasions, and have failed to perceive any tonic effect, the idea is immediately suggested, that the fault lies in the operator, and not in the agent or method employed. The successful employment of general faradization requires, of course, a certain amount of anatomical and physiological knowledge, but it is not for lack of this that so large a proportion fail to appreciate its power. The most thorough students of the principles of electro-physiology are frequently among those who are most deficient in the practical manipulating skill that comes only from long experience and patient labor. If it were possible, as it is not and never can be, to relegate the administration of general faradization to nurses and attendants, the method would undoubtedly soon come into very general use, and its remarkable therapeutic powers, especially as a tonic, be everywhere recognized. Dr. Vater, of University of Prague, has, in a series of articles in "The Wiener Medicinische Zeitung," borne abundant testimony to the wide and varied therapeutical effects of general faradization. Instead of subjecting the method to the test of theory alone, and then in his ignorance rejecting it, he has put it to the severer and more conclusive test of a patient and discriminating clinical investigation. He concludes that if the nervous system be thoroughly influenced, and the muscular tissues not too violently, but passively exercised, tonic effects may be pretty uniformly expected; that they are more readily observed in nervous organizations, and that they are as permanent as those following any other remedy.

Benedict, one of the most able and indefatigable of investigators, says that, "especially in insomnia, even of humatics in migraine and general nervousness, he has observed the most beneficial results." In general galvanization, substantially the same processes are to be followed out as in general faradization, substituting of course the galvanic for the faradic current. It is not often that this method (somewhat heroic certainly, if any considerable strength of current be used) is indicated in the treatment of disease. It produces effects too profound both reflexly and directly on the central and peripheral nervous system, to be tolerated in the majority of those conditions of nervous prostration that so readily amend under general faradization.

All who have had a wide practical experience in electro-therapeutics have undoubtedly on occasions found themselves surprised and in perplexity on account of the remarkable insusceptibility of certain cases to the influence of the ordinary methods of electrization.

Some years since, I observed in a patient suffering from disease of the supra-renal capsules, this insusceptibility to a marked degree.

In its relations to electricity, the nervous system seemed to be profoundly anæsthetic.

The patient was perceptibly strengthened by general faradization, although it was necessary to use enormous power to make any sensible impression upon him, but beyond a certain point of improvement these applications failed to be operative. The patient was then submitted to general galvanization. The usual

effects of galvanization of the cervical portion of the cord and sympathetic, viz., metallic taste, increased flow of saliva, and involuntary contractions of the œsophagus, became manifest only under currents of considerable tension, and the power that the patient could bear without inconvenience far exceeded what was obtainable from the thirty-six-cell apparatus that I had at hand.

A decided improvement was immediately manifest in the condition of the patient, and as his strength increased it became in due proportion more and more susceptible to the influence of the applications.

TRACHEOTOMY AS A PRELIMINARY TO EXSECTION OF THE SUPERIOR MAXILLA.

EXTRACT FROM REMARKS ON TRACHEOTOMY MADE BEFORE THE KINGS CO. MEDICAL SOCIETY, BROOKLYN, N. Y., OCT. 19, 1875.

By LEWIS S. PILCHER, M.D.,

ADJUNCT SURGEON, LONG ISLAND COLLEGE HOSPITAL, N. Y.

TRACHEOTOMY is of interest to the operative surgeon in connection with operations involving the cavities of the mouth and nose, attended with profuse hemorrhage; more especially that for removal of a part or the whole of one of the superior maxillæ. To those familiar with these operations no words are needed to magnify the difficulties which arise from the impossibility of maintaining complete anæsthesia, and from the dangers of the blood entering the larynx. The haste of the surgeon, the struggles and cries of the half-anæsthetized patient, and the free hemorrhage make the scene one of the most startling of any incident to the surgical art. In such cases as these it is that tracheotomy presents itself as a measure preliminary to the more important surgical procedure, whereby the special terms and difficulties of such operations are removed, and it made possible that the most extensive and delicate operations about the mouth and nose should be conducted with as much care and deliberation as in any other part of the body.

I have been able to prove this in my own experience in a case of tumor of the superior maxilla, in which I was called upon to operate by Dr. P. R. Cortelyou, of this city, under whose care it had been.

The patient was a lady, over sixty years of age. Less than six months had elapsed since any trouble about the face had been noticed. The external deformity was but slight. It had encroached as yet only upon the nasal passages, and every indication pointed to an easy and thorough eradication of the entire diseased portion. At the earnest request of the patient, the operation was undertaken. Tracheotomy was performed as its first step, and during the remainder of the operation, ether was administered through the tracheal canula. As the operation progressed, the disease was found to be far more extensive than had been expected. The entire superior maxilla, with the palate, the lateral mass of the ethmoid, and the body of the sphenoid were infiltrated with, or largely replaced by, encephaloid material. It was impossible to remove all without opening the cavity of the cranium, short of which only I desisted. Troublesome hemorrhage was experienced only from the posterior palatine artery. This was quickly controlled by the galvano-cautery in the hands of Dr. Geo. R. Fowler. The patient rallied from the operation and lived for more than a month, finally succumbing to cancerous disease of the liver, which rapidly developed itself after the removal of the first growth.

But it is not for the purpose of recording all the details of this interesting case that it is reported. It may indeed be a question whether the operation ought ever to have been undertaken. Be that as it may, no case could possibly illustrate more forcibly the great value of a preliminary tracheotomy in extensive and complicated operations involving the nasal and buccal cavities. An amount of care and deliberation, of thoroughness and confidence in each step of the operation was secured, which otherwise would have been impossible, however bold, confident, skilful, and experienced the operator might have been. That I am not alone in this opinion I am persuaded by the exclamation of one of the older and more honored physicians of this city, who was present at this operation, that he hoped he would never again see excision of the upper jaw attempted without tracheotomy first having been done. A similar feeling had been experienced by myself more than two years ago, when I witnessed an excision of the superior maxilla by Prof. Wm. Warren Greene, and extirpation of an eye by Dr. Prout, in the same patient, in immediate succession, tracheotomy having first of all been done.

This method of procedure was adopted by Dr. Jas. L. Little, of New York City, last winter, in operating for removal of a large fibroid tumor, occupying the posterior nasal and the upper pharyngeal region, with brilliant success. I am informed that this use for tracheotomy has of late obtained large favor among certain German surgeons, but of this I have no data. I make no pretence of making an exhaustive discussion of the history of this use of tracheotomy. I have desired merely to take the opportunity, when attention is being directed to this operation in its general relations, to call attention to this one use to which it has been put. I am aware that it may be objected that tracheotomy adds new elements of danger to dangers already great enough. But I believe that an examination into its merits will compel the conclusion, that its dangers are too slight to be permitted to outweigh the benefits which its performance brings.

In the adult, performed with deliberation, through healthy tissues, the tracheal wound kept open but for a few minutes, it becomes a comparatively simple and innocent proceeding.

TRANSACTIONS OF THE MEDICAL AND CHIRURGICAL FACULTY OF MARYLAND. Seventy-seventh Annual Session, held at Baltimore, April, 1875.—This pamphlet of 226 pages contains the minutes of the meeting, reports of officers and committees, lists of members, and the following papers: Annual Oration: "Contribution to the Medical History and Physical Geography of Maryland," Joseph M. Toner, of Washington, D. C.; "Report on Surgery," Thomas R. Brown; "Report of Section on *Materia Medica* and Therapeutics," Richard McSherry; "Report of Section on Obstetrics and Gynecology," William T. Howard; "Report of Section on Anatomy, Physiology, etc.," W. C. Kroman; "Surgical Cases in Foreign Hospital Practice," G. H. Boyland; "The Contagium Particles of the Eruptive Contagious Fevers: their Nature and Mode of Action," J. E. Atkinson; "Tinnitus Aurium: a Consideration of the Causes upon which it depends, and an Attempt to explain its Production in accordance with Physical Principles," Samuel Throald; "On Altitude and Climate in the Treatment of Pulmonary Phthisis," W. Gleitsmann; "Importance of the Galvanic Current in Electro-Therapeutics," F. T. Miles; "Digitalis in Cardiac Disease," S. C. Chew; "Treatment of Paralyzed Muscles by Elastic Relaxation," John Van Bibber.

Original Lecture.

CLINICAL LECTURE ON A CASE OF TYPHOID FEVER

COMPLICATED BY INTESTINAL HEMORRHAGE AND
BRONCHIO-PNEUMONIA.

By FRANCIS DELAFIELD, M.D.,

ADJUNCT LECTURER ON PATHOLOGY AND PRACTICAL MEDICINE IN THE
COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

GENTLEMEN:—The case before us suggests a few points relating to the treatment of typhoid fever. The history of the patient is as follows: She is twenty-eight years of age, and was admitted to the hospital September 11th, 1875. She then stated that she had enjoyed an average degree of health previous to her present illness, but that on the 6th of September she began to feel "creeping chills" over her body, which continued more or less up to the time of her admission, and were accompanied by headache and fever. Upon admission her temperature was found to be 102° F. in the morning, and 103½° F. in the evening; there was slight tenderness in the right iliac fossa; there was no tympanitis, however, but there was a slight amount of bronchitis. From the time of her admission up to the 23d of September her temperature was 102° F. in the morning, and 104–104½° F., and occasionally 105° F. in the evening. The patient during all this time was quite comfortable, and did not appear to be suffering from severe constitutional disturbance. The tongue was slightly dry; there was a slight accumulation of sordes, and there was a little diarrhoea—from two to four discharges every twenty-four hours. Her treatment consisted mainly in the administration of food, chiefly milk, and an occasional sponging of the body with cold water. Although from the 11th of September until the 23d of that month her temperature was constantly elevated, she received no cold baths, but merely took her regular supply of milk: sometimes a small amount of whiskey was added to the milk, when the pulse was not as good as desired, and from time to time she was sponged off with cold water.

On the 23d of September she began to have hemorrhage from the bowels. This continued for several days, and at times considerable quantities of blood were discharged, so much so that it was deemed wise to endeavor to arrest it.

For this purpose tablespoonful doses of the following mixture were administered every three or four hours:

R. Ac. gallic.....	ʒ i.
Ac. sulph. ar.....	ʒ ij.
Syr. aurantii.....	ʒ ij.
Aque.....	ʒ iv.
M.	

Under this treatment the hemorrhage was soon arrested and has not returned.

Between the 25th of September and the 5th of October her temperature gradually became lower, both in the morning and in the evening, so that at the latter time it rarely went above 103 or 103½° F. During this time the diarrhoea continued to a moderate extent, but was easily controlled by the administration of opium.

On the 30th of September she was ordered a mixture, consisting of the sulphate of quinine and dilute sulphuric acid in such quantities that each dose contained three grains of the quinine and twenty drops of the

acid. This was administered three times a day. On the 5th of October, the temperature remaining about the same, a physical examination of the chest was made, and over both lungs were found evidences of broncho-pneumonia, namely, areas of dulness and sub-crepitant râles.

Here then was one of the reasons probably why the disease had lasted for so long a time. On October 10th her morning temperature for the first time was $99\frac{1}{2}^{\circ}$ F., and the evening of the same day it was $102\frac{3}{4}^{\circ}$ F. Since that date until the present, October 26th, the temperature has been gradually falling, and has finally reached 99° F. in the morning, and 101° F. in the evening. The diarrhœa has gradually diminished, and the passages have become quite natural. The physical signs in the lungs have almost entirely disappeared. At no time has the patient had any cough.

Such is the general outline of the history of the case. Just at present the treatment of typhoid fever by means of cold baths or cold affusions, or by the administration of quinine in large doses, is much in vogue. The theory of this treatment is based upon the assumption that the chief cause of death in uncomplicated cases is a long-continued elevation of temperature.

This doctrine is derived chiefly from the teachings of Liebermeister. It is assumed that the greater number of deaths from typhoid fever are due to the effect of the fever heat. As a direct result of this fever heat, we are pointed to the parenchymatous degeneration of the muscles and viscera found after death. We are told also that paralysis of the heart is a frequent cause of death, and that this paralysis is due to a degeneration of the wall of the heart, resulting from the fever heat.

I think, however, that these views are as yet assumptions rather than facts.

In the patients who have died from typhoid fever in New York during the past five years—not a large number—degeneration of the muscles has been the exception and not the rule. Parenchymatous degenerations of the spleen, liver, and kidneys, however, are very frequent. But are we warranted in asserting that these degenerations are only the results of the fever? I think not. For we find the same degenerations in other diseases which are rather marked by their malignancy than their high temperature. In puerperal peritonitis parenchymatous degeneration of the glandular viscera is almost always found, although the disease may not have continued for more than twenty-four or thirty-six hours, and by no means is necessarily associated with a high temperature. I have even seen it in peritonitis without any elevation of temperature. So also the same changes are found in fatal cases of pyæmia, in the more severe forms of pneumonia, and are sometimes seen in the viscera of patients who die from cerebro-spinal meningitis. In other words, in those patients who die from diseases which are strongly marked by constitutional symptoms, or run a peculiarly malignant course, we very commonly find parenchymatous degeneration of the glandular viscera.

The disease in which such parenchymatous degeneration is specially marked is acute atrophy of the liver, and this may be attended with a very moderate increase of temperature. Still farther, in many patients sick with typhoid fever there is enfeebled action of the heart, but such an enfeebled action is not by any means always in relation to the severity of the fever. It is not in the patients who have the highest temperature that the heart's action is always the most deranged. On the contrary, in some of the very mild-

est cases of typhoid fever, and also in some of these cases at a very early period of the disease, we may meet with enfeebled action of the heart. For example, such a case as would be marked by a morning temperature of 99° F., and an evening temperature of 102° F., and one which has lasted for a week, may give us well-marked feebleness of the heart's action, as indicated by a soft diærotic pulse and a feeble first sound. In these cases the character of the pulse can be improved at once, as a rule, by a proper administration of stimulants.

So much for the theory upon which the treatment is based. The treatment itself, on the other hand, is very excellent in appropriate cases. When judiciously used cold baths may save the lives of very many patients, hence the treatment is one worthy of every consideration. You may ask why did we not give this patient cold baths? I do not think we are to judge of the necessity for the use of baths merely from thermometrical observations. I do not believe that the thermometer alone is a sufficient guide for their use, but that we must rather look at our patients, and determine what effect is being produced upon them by the fever. It happens very frequently that patients with a temperature of 101° F. suffer much more severely than others with a temperature of 104° F., or even 105° F. In other words, we are to be governed in determining the necessity for cold baths by the general appearance of the patient. If the patient has dusky cheeks, a dry mouth, a rapid respiration, with bronchitis and a burning heat of the skin, which can be appreciated as well by the hand as by the thermometer, you have a proper case for the use of cold baths. But in such a patient as the woman before us, whose temperature has been high, it is true, but whose skin has been slightly moist and comparatively cool to the touch, who has not suffered from severe diarrhœa, nor had a very dry tongue, scarcely anything would have been gained by the use of the bath. In a case where the use of cold becomes a necessity, the full cold bath is the very best form in which it can be employed. Place the patients in a large bath tub containing water at about 70° F., and let them remain for ten minutes, and repeat such a bath every two hours, if necessary, until their general condition is improved.

LOBULAR PNEUMONIA.

A bronchitis in cases of typhoid fever is an ordinary complication, but if an ordinary bronchitis becomes capillary, or a lobular pneumonia is developed, the condition of the patient is at once rendered seriously worse, and the temperature is commonly kept elevated, as it was in this case. The elevation of the temperature was the only natural symptom that this woman presented as indicating the existence of lung complication, and it was only by physical examination of the chest that the lung consolidation was detected.

Patients with typhoid fever apparently are capable of acquiring two entirely different kinds of broncho-pneumonia, and the probability of recovery, or of going on in the development of phthisis, seems to depend upon the kind acquired. If they acquire a simple broncho-pneumonia, such as was present in this case—a bronchitis complicated with a pneumonia—in which the air-cells were filled with the products of inflammation, but without any interstitial inflammation, they are very apt to recover. The consolidated portions of the lung resolve and the patients gradually get better.

If, on the other hand, the broncho-pneumonia, instead of having this simple form is a bronchitis accompanied by an interstitial pneumonia—a pneumonia

and the walls of the air-cells and the interstitial connective tissues of the lung—then there is produced consolidation of lobules of lung tissue in which there is little or no tendency to resolve. They remain, and after remaining for a certain length of time these nodules become cheesy, and then the patient exhibits the regular symptoms of phthisis.

This is the manner in which a certain number of patients die who have had typhoid fever. They die of phthisis after having the fever, and the phthisis depends upon the development of a broncho-pneumonia, which involves the interstitial tissue of the lung and the walls of the air-cells, and shows but little tendency to resolve.

At the beginning of a broncho-pneumonia there is no way by which you can determine whether the one or the other of these conditions is present. This can be decided only by the progress of the case. But that there is such a difference in the type of the broncho-pneumonia, and that one is much more likely to proceed to a fatal termination than the other, I feel certain from the examinations which I have had the opportunity of making in such cases.

Progress of Medical Science.

TREATMENT OF BROKEN NOSE BY FORCIBLE STRAIGHTENING AND RETENTIVE MECHANICAL APPARATUS.—Mr. William Adams thinks that the subject of broken nose is one which has not been sufficiently noticed by the profession, notwithstanding that the resulting deformity and the interference with the voice and breathing are sometimes very great. He divides the so-called cases of broken nose into two classes, viz., (1.) Those in which the injury is limited to the anterior or cartilaginous portion of the nose, and consists essentially of depression, with lateral bending of the cartilaginous septum; a partial displacement of this septum from its attachment to the vomer also occurring in many cases. (2.) Those in which the nasal bones are fractured, in addition to the depression and displacement of the cartilaginous septum from the vomer. His plan is to straighten the bent cartilaginous septum and bring it into a direct line with the vomer, using for the purpose a pair of strong forceps with flat parallel blades, introducing the blades into the nostrils, and, in case of fracture of the nasal bones, raising these also by carrying the blades directly upwards.

External pressure can also be made by the hand to aid in the accurate adjustment of the parts. After this procedure he uses a steel compressor, consisting of two blades, joined together at their bases and moved by a screw, so as to approximate or separate the blades, which are inserted into the nostrils so as to support the septum, the screw being only tightened sufficiently to bring the blades into contact with the septum, but without making any pressure upon it. This apparatus can be worn for two or three days and nights without removal. After this he introduces into each nostril an ivory plug, which can be removed and reintroduced by the patient at pleasure, so that both nostrils are kept moderately distended, and support given to the cartilaginous septum.

Support of the nasal bones by any plug introduced in the upper part of the nasal cavity would be impossible, owing to its small size, and the sensitive character of the lining mucous membrane. For fractures of

the nasal bones, Mr. Adams has used a retentive apparatus externally, consisting of a pad, adjusted by cog-wheels, and attached to the front part of a steel band, passing round the head, forming, as he says, a kind of nose truss. This truss can be worn, he says, for two or three weeks, according to the extent of the injury, and in a case referred to in his article, it was worn for a still longer period.

This forcible straightening of the nose does not have to be repeated, except in cases of great severity. In none of the cases which he cites did he have the opportunity of applying the treatment within a month after the accident, and he thinks that undoubtedly its employment would be more easy and more effectual in proportion to the early period at which it was employed after the accident; but, of course, should there be much swelling and ecchymosis, it would be better to wait until these symptoms had subsided. In recent cases, however, it may not always be necessary to employ any retentive apparatus.—*The British Medical Journal*, Oct. 2, 1875.

ANDRAL ON GLYCOSURIA.—In the *Gazette hebdomadaire* for April 16th, 1875, we find an analysis by Andral of eighty-four cases of glycosuria of which he had kept notes. It appears that the disease is very rare under 20 years of age, less rare between 20 and 30, most frequent between 40 and 50, little less so between 50 and 70, and very rare after the latter age. Of the eighty-four there were fifty-two males and thirty-two females. Various nervous affections seem to have an influence in developing or aggravating the glycosuria; a deficiency of food amounting almost to starvation led to the disease in four cases. On the other hand, Andral has observed that many of these patients have been notably strong and vigorous before the development of the diabetes. An accidentally complicating disease will often cause a temporary diminution of the sugar eliminated: as for example an angina and a dysentery. A degree of hereditary influence was observed. While the general circulation ordinarily exhibits no lesions, the capillary circulation often does so, as, e.g. in swelling and redness of the gums, injection of the conjunctiva, erythema of the skin and congestion of the lungs. There were four cases of gangrene among the eighty-four; viz. once in the lungs, and three times in the feet and legs. The acid reaction of the saliva that has been observed may be due, according to Andral, to an admixture with the ordinary mucus of the mouth. At the autopsies he constantly observed congestion of the liver and kidneys, attributable in the latter, at any rate, to excessive functional activity. There was also a peculiar induration and dryness of the spleen. Tubercular granulations were commonly found in the lungs, which Andral regards as secondary deposits due to the debility caused by the diabetes. No new points were brought out regarding treatment.

PRODUCTION OF RED BLOOD-GLOBULES IN TYPHOID FEVER.—M. Cornil has found in the blood of the spleen of patients who have died in the third week of typhoid fever, large numbers of white globules, enclosing red globules to the number of five, six, or even more, in a single cell. Other cells enclosed granules of hematosine. Although the existence in the blood of these large cells containing red globules is nothing new, nevertheless Cornil is the first to insist upon their multiplication in typhoid fever. The mesenteric glands, according to Cornil, are always inflamed in typhoid fever, in a manner analogous to the acute or subacute inflammation due to suppurative lymphangitis.—*Lyon Médicale*, Aug. 22, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

New York, November 20, 1875.

NEGLECTED BRANCHES OF MEDICAL STUDY.

WHEN we scan the schedules of lectures in the medical colleges in their busiest seasons, we find an amount of occupation outlined for the whole didactic course, apparently over-sufficient for the grasp of ordinary scholastic minds. If we had not ourselves passed through the same ordeal, we might naturally wonder what time was left for the student, wearied with a continuous train of lectures, clinics, dissections and examinations, to minister to such slight personal attentions as are embraced in the provinces of eating, drinking and sleeping. That the branches taught must be considered by their teachers good and amply sufficient, may be inferred from the fact that the best of our schools have plodded along in the same groove for a number of years, with but little change of programme. So far as length of study, methods of examination of candidates for graduation, and similar very practical matters are concerned, we have at this moment nothing to observe; these have often been discussed and are still amenable to a just and rigid scrutiny. It might seem like superfluous criticism for us to intimate that this mass of learning, which is to be packed away in a winter's session, has in it any element of insufficiency; and yet it is evident, at the most superficial glance, that several branches which may in due season become all-important to the practitioner, receive no attention at the hands of the lecturer, or are clothed in the scantiest of material to hide the nakedness of their treatment. Notably among these may be mentioned Medical Jurisprudence, Pharmacy, and Practical Hygiene, while Chemistry is too often taught tediously in all its non-medical minutiae, its medical relations being accidentally hinted at only when a convenient occasion arises. The History of Medicine is necessarily pushed aside, far out of sight, by the more practical branches, and left as an after-study for the curious and an accomplishment for the professional virtuoso. Half

a century ago, however, when the University of Virginia was founded, even this last subject was embraced, with the other neglected branches just named, in the curriculum of instruction. Needing most of these important aids when he settles down to the sterner realities of medical life, the graduate finds when he has most urgent occasion for their service, that some of the tools which he is expected to skilfully handle are rusty from disuse, and that he must hastily get them in order for the emergency in which they are to become of practical utility, after his own untutored fashion, perhaps nervously and imperfectly, at a time when the eyes of a whole community may be fixed upon him. He may be pardoned at such a moment for thinking that the system of instruction which seemed so perfect to him as a student must have been full of glaring deficiencies.

So far as the teaching of Pharmacy is concerned, there is no reason why it should be so thoroughly isolated from the medical courses, and left entirely to the pharmaceutical colleges. Thousands of medical men throughout the country are necessarily their own apothecaries, and many of them travel in a circle as prescribers in the well-trodden footsteps of their routine-loving preceptors, often confining themselves to the employment of a few old-fashioned remedies, merely because they have never had imparted to them during their student-life the general principles of manipulation and preparation of drugs and chemicals. They are only roused to a just appreciation of the claims of Practical Hygiene, when a virulent epidemic "at one fell swoop" simultaneously sweeps away their patients and their own reputation as skilful practitioners. They then impatiently overhaul their text-books, and "when found, make a note of it," for the next epidemic, which may never visit them; but their attention has never been excited to the means of prevention of the more common diseases which are daily present at their very elbow. Medical Jurisprudence is shamefully neglected; a mere smattering of information as to its toxicological relations is sometimes acquired in the schools from incidental mention by the teacher of the department of *Materia Medica*, but the great mass of the profession is woefully ignorant of the medico-legal complications in which practitioners may sometimes be seriously involved. It should be borne in mind that medical experts are not the only ones who are likely to be summoned as witnesses in judicial cases. Every village doctor may some time or other occupy a creditable or a ridiculous position on the witness-stand, according to the extent and variety of his information on questions of medico-legal import. In many of the schools, Medical Jurisprudence is tacked on as a supplement to another branch, in some of them a teacher being in the same session professor of both Institutes of Medicine and Medical Jurisprudence; but, even when so taught, it occupies but a subordinate place, not at all commensurate with its merits,

and under such circumstances still deserves to be classed among the almost neglected branches. Occasionally it is offered to slender summer classes as a temporary placebo, but although sometimes excellently taught, it even then does not assume its deserved prominence, and fails to reach in its influences the greater masses of the more important winter classes, from which the ranks of the profession are most numerously recruited.

Reviews and Notices of Books.

THE BORDERLAND OF INSANITY. By ANDREW WYNTER, M.D., M.R.C.P., London. New York: G. P. Putnam's Sons, Editors.

This book is composed of a collection of papers on insanity and collateral affections. Its title is attractive, if its subject is not; but the treatment of it is rendered acceptable, and sometimes attractive to non-professionals, by the clearness of the exposition and common-sense of the judgments.

Almost everybody will be attracted by the title of the book—which is also the special subject of the first essay—to know how far they are in or out of the borderlands of insanity. For the peace of mind of most readers the question is solved, not didactically, but historically, in a series of anecdotes, out of which the reader may choose to make or not the application to his dear self.

The chapter on *Non-restraint in the treatment of the insane* is the most thorough and far-seeing. It comprises the early history of the treatment by faith, by fear and force. It recites the efforts of Pinel (1792) to Conolly (1840), as if the two were from the same heart and mind. It shows that to the brutality of the treatment of George III., during a fit, is due the Parliamentary inquiry of 1815, which turned the scale towards humanity to the insane. It is far from approving of the *reform* which does not compress the insane in iron manacles, iron cages, etc., but confines them, of all classes and degree, in long lonely halls, where they can enjoy the sight of each other, or worse still, to crouch behind a door, shutting their eyes with their fist, or covering them with a curtain of their hair, either dumb, mute, or yelling with rage or desperation. Dr. Andrew Wynter does not give his approval to the bills of expense incurred in the erection of palaces, which, far from being the proper treatment of the insane, are little more than enlarged strait-jackets, made of stone. He turns a regard, as of hope, toward Gheel, where the insane are free in a cottage or hut, with his *mourrier* and family, partaker of their board, labors, pleasures, beer, pipe, etc. The narrative shows that it is made up from descriptions—Dr. Webster's, Nenschler's, etc. But Dr. Wynter does not appear to have visited the quaint old village, otherwise his sense of observation would have made him contrast the satanic expression of the insane of the *restraint* (as painted without exaggeration by Hogarth), the empty or searching look of the shut-up ones, with the undiscernible countenance of the hosts of the Gheel's peasantry.

If Dr. W. had visited this place he could have seen that Ste. Dymphna is rather antagonistic to the present treatment. The writer of this note had the honor of a

conversation with a *Beguine* attached to the church, who, thinking he was in quest of a place for some relative, told him distinctly that the doctor beyond was losing all his patients; that they, in the building adjoining the church, could alone cure mine; and she proceeded to show the *institution*—a room with two beds, a closet with another, garnished with chairs, and a benign St. Francis, looking towards the empty couch. They brought there the rude iron probang, fork, and other instruments, to force the patients to eat, to be silent, motionless; the old (*poire d'angoisse*) chokepear, etc. The middle room had a most serious aspect. An immense stone chimney, with rings in the wall, below for the legs, higher for the wrists, following an oblique line from a corner of the hearth to its axis; nothing else, but opposite an oaken gallery, wherefrom could be securely directed the torture, exorcism, and the other Christian parts of the *moral treatment*; for, said the *Beguine*, insanity, being a disease of the mind, must be treated by spiritual means; so said Torquemada. However, the rusty rings do not seem to be now used.

The skilful physician of the asylum, Dr. Bulkens, has a great deal to ignore about this holy place. His predecessor, Dr. Parigot, though a man of great energy, had his back broken by Ste. Dymphna, who is determined to defend dearly her last days of practice. Considering the impossibility under which Dr. W. labors of telling everything about Gheel, his narrative is very interesting.

Of the other parts of the book, we will mention only *the training of the imbecile*, which is truly a topic belonging to the *Borderland of Insanity*.

The subject is treated from a purely English point of view, which gives its treatment a character and a weakness. The introduction, in which the treatment of idiots in county poor-houses or at home is shown insufficient, does not leave anything to desire; the history of the institutions is bare from the picturesque enthusiasm with which devoted women, Drs. Reed, Conolly, and others, aroused even royal blood in behalf of their protégés. The Colchester asylum, Essex Hall, is sufficiently described, and the great Earlshood asylum is expatiated upon at great length. The training of the children takes a part, their peculiarities another, and the qualities of the late superintendent, Dr. Langdon Down, the third of the narrative. The episode of the idiot who built a model of the *Great Eastern* is well told; more on the technicalities of the training would have spoken well for the competency of Dr. Wynter to treat this question; but it would have been easy to go in it too deep for the average of readers. For this average, the remnant of the book contains good, simple, and practical advice, referring to the several emergencies in which women and men may need the support of strong reason to keep on the right side of the borderland of insanity.

For the English public, the book does not contain the description of the asylums for idiots, of Normanfield, Lancaster, and others of more recent creation; and for the American public a comparison of our institutions for feeble-minded children with the English would have been highly interesting. But everything cannot be comprised in a small volume, printed in large type, and easy to read, even by those who are on the borderland of insanity.

THE DISEASES OF THE HEART AND OF THE AORTA. By THOMAS HAVDEN, of Dublin, Ireland. Reprint by Lindsay & Blakiston. 1875.

A TREATISE on the diseases of the heart and of the aorta, in two large octavo volumes, comprising alto-

gether more than 1,200 pages, appears to be a ponderous and uninviting work. And yet a study of Dr. Hayden's book convinces us that there is not an unnecessary page. It really constitutes a small library on the subject of which it treats. So comprehensive and so full are the quotations from every author of any note, that we can learn from this book alone almost everything which is now known concerning the anatomy, physiology, and diseases of the heart.

The chapter on the physiology of the heart, the causation of the heart sounds, and the rhythm of the cardiac cycle is fairly exhaustive.

All the published theories concerning the causation of cardiac murmurs are given. The author, however, does not admit of the existence of pure tension murmurs. He holds that murmurs are dependent on vibration, and the essential cause of such vibration is the friction of the blood current. He admits of murmurs occurring before systole, with systole, after systole, with diastole, and after diastole.

Murmurs produced at the tricuspid valve are to be heard, says the author, within an area of an irregularly triangular figure, having its base at the level of the ensiform cartilage, and extending from the middle line of the sternum to a point in the left fifth intercostal space about an inch to the inside of the apex. The vertex of this triangle would correspond to the lower edge of the left fourth costal cartilage near the sternum; and its sides to two oblique lines connecting this with the extremities of the base.

Of the presystolic murmur he gives a very full account. He assigns the honor of identifying it to Fauvel in 1843. He believes:

1. That presystolic murmur is pathognomonic of auriculo-ventricular narrowing;
2. That it is never present where auriculo-ventricular narrowing does not exist;
3. That it is never permanently absent in cases of this lesion, and that it is very seldom temporarily absent.

Pericarditis, diseases of the substance of the heart, endocarditis and diseases of the valves, bloodclots and neuroses of the heart, are all treated of in the same complete and satisfactory manner. Not the least valuable feature of the work are the tables of cases of the different varieties of disease, compiled in large measure from the Transactions of the Pathological Societies of London and Dublin.

PRESERVATION OF MORPHIA SOLUTIONS.—It is asserted by M. Vidal, that the addition of chloral to a solution of morphia renders it much less liable to spontaneous change. This fact, if it be true, is important. The alteration which concentrated solutions of morphia undergo renders their strength variable and uncertain if they are laid by for a time. M. Vidal adds to the solution a quantity of chloral equivalent to twice the weight of the morphia it contains. He affirms that the injection of this mixture is not painful.

THE SUNFLOWER AS A PREVENTIVE OF MIASMA.—A correspondent of the *Soil of the South*, writing from a place in Alabama, which he says was peculiarly subject to fevers, gives the result of his experience in the premises, and in not a single instance where he planted sunflowers around his negro cabins did their inmates suffer from fevers; while his wife, two children, and two house servants, all had fevers, he not having planted any of the sunflowers around his own dwelling, which, in his opinion, accounts for the difference in the results.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 27, 1875.

DR. F. DELAFIELD, PRESIDENT, IN THE CHAIR.

METASTATIC ROUND-CELL SARCOMA OF LUNG.

DR. C. HEITZMANN presented specimens of sarcoma, with the following written history:—

This specimen of tumor was removed from the body of a man, aged 69 years. It had existed in the groin as a wart-like prominence, the size of a pea, ever since birth, and had not troubled him until within the past three years, when it became sensitive, and the patient desired its removal. Dr. Schönhey, the attending physician, performed the cauterization by means of nitric acid, which after several applications proved satisfactory, the surface healing kindly. A few months afterwards there appeared a hard infiltration and ulceration on the place of the scar, which were not present at the time of the first operation. In the course of eight months the infiltration developed to the circumference of the palm of a hand, and the height of about three-fourths of an inch. This tumor was extirpated by Dr. Schönhey, by means of Maisonneuve's *fêches*. After the slough fell away, there appeared a healthy-looking granulating surface, and this healed up within a fortnight.

In the course of a month a growth reappeared in the neighborhood of the almost invisible cicatrix: first outward of it, but afterwards towards the serotum. These tumors grew gradually, forming several elastic, pretty soft nodules, altogether of the size of a man's fist. The growth was now declared, by several prominent consulting surgeons of this city, as cancer, and ulceration was expected. Meantime the patient became exhausted, emaciated, his right leg œdematous; he began to suffer from cough, finally from dyspnea, and he died, after severe suffering, at the age of 69 years, in February this year, two years and eight months after the first operation.

A few weeks before death, I got, through the kindness of Dr. Schönhey, the sputa of the patient, and by microscopical examination of the sputa I was enabled by the presence of copious round elements, provided with large nuclei, to make the diagnosis of round-cell sarcoma tumors in the lungs, which being metastatic or secondary tumors, allowed the diagnosis of the presence of a tumor of the same kind in the primary locality. The post mortem examination, made by Dr. Schönhey, proved the presence of innumerable grayish-white nodules in both lungs, of the size of a millet-seed to that of a walnut; namely, secondary sarcomatous tumors. The original tumor in the right groin showed nodes of almost walnut size, of a bluish-red color, and of a pretty soft consistence, which were separated from each other by a small amount of connective tissue. The covering skin was thinned, extended, but nowhere ulcerated.

The microscopical examination shows a tumor of rather uncommon construction. We see very large elements either of the appearance of epithelium, or that of ganglia arranged in irregular rows within the delicate connective tissue, moreover also in irregular alveoli. On other places we find an infiltration of the connective tissue, with large elements, alike those of round and spindle-cell sarcoma. Plenty of relatively

large capillary blood-vessels are to be seen, even in the midst of sarcomatous elements.

We then have to deal with a tumor, called by Billroth "alveolar sarcoma," partly exhibiting the exquisite feature of a round and spindle-cell sarcoma. Apparently the tumor was first of all a cancer, growing out of a papillary wart-like tumor, which by and by, after being operated upon, changed its character to that of a sarcoma. That, however, the tumor is a real sarcoma is proved by the presence of the secondary tumors in both lungs.

NEUROMA IN AXILLARY SPACE, IMPLICATING MUSCULO-SPIRAL—OPERATION.

Dr. C. K. BRIDGON presented a specimen of the above, with the following history:—

Mrs. Sophia Davis, native of New Jersey, consulted me during the past summer (1875) in relation to a tumor which had been present in her axilla for some years.

She informed me that twenty-five years ago she began to suffer pain, concentrated in a small space over the back of the right wrist joint; it was unaccompanied by heat, redness or swelling, and gradually increased in severity, until after years had elapsed it would at times amount to almost unendurable agony. Four years ago this pain began to radiate downwards to the thumb, index, and middle finger, and she began to suffer from pains in the arm and fore-arm, involving the whole extremity, but most acute in the posterior and outer regions; the character of these pains varied—at times a continuous aching, more frequently lancinating, and associated with sensations as if needles were being thrust into the part; at other times sensations of creeping and crawling; but the most severe were the lancinating pains, which would occur so frequently as to prevent her obtaining more than two or three hours' sleep out of the twenty-four. No treatment has afforded her the slightest alleviation. When the pains began to shoot up and down the limb she commenced the use of faradization, and it was at that time that the tumor was first discovered; it was then very small, but under the stimulus of the current it rapidly developed in size, and the pains became more intense.

Present Condition.—Patient is a woman of fifty-eight years, and looks young considering the pain she has endured for so long a time; she is of spare habit; her right upper extremity appears to be as well nourished as its fellow, and there is no anesthesia or motor paresis. In her axilla is a tumor about the size of a billiard ball; it is situate apparently about the centre of the space, bulging the anterior wall slightly, the floor scarcely at all; it can be moved readily from before backwards, but not in the direction of the axis of the limb; traction on the tumor causes pain which radiates down the back of the arm, forearm, and hand; pressure applied from before backwards produces pain in the whole extremity.

Diagnosis.—The pain which centred for so many years over the back of the wrist was probably situate in the gangliform enlargement of the posterior interosseal branch of the musculo-spiral, which distributes filaments to the ligaments and articulations of the carpus. For a long period of time the radiating pains were confined to those territories supplied by the musculo-spiral, but as the enlarging growth involved the associate branches of the plexus, the whole extremity became affected, and it was more difficult to analyze the distribution of pain.

Prognosis.—As to recurrence if removed, very doubtful; equally so regarding pain, which sometimes persists after section or removal of a portion of nerve

that has been the seat of persistent neuralgia. We have also to take cognizance of the local changes that will probably ensue in parts supplied by the nerves—disturbances of nutrition, wasting and contraction of muscles, annihilation of sensibility, diminution of temperature, possible affections of joints, skin and its appendages.

I expressed an opinion, based upon the whole history of the case, that the tumor in the axilla was a neuroma involving primarily the musculo-spiral at or near its origin from the plexus, and I advised its early removal.

Operation was made October 20th, 1875, at 11 A.M., in the presence of Professors Erskine Mason, John T. Darby, Chas. A. Budd, and Drs. John Howe and Stephen J. Clark. An incision six inches long was carried from the humeral to the thoracic boundaries of the axilla, midway between the anterior and posterior folds. After division of the superficial and deep fascias, the dissection was continued down until the areolar investment came into view; this was freely opened, the knife was laid aside, and the capsule was stripped from the tumor by aid of the fingers alone. When half the growth was separated from these connections, the internal cutaneous nerve came into view, closely embracing its thoracic aspect; this was detached by the fingers and the handle of the scalpel, and was drawn inwards. On the humeral side the ulnar nerve was exposed, separated, and drawn outwards. Both these nerves were adherent by connective tissue, but were not incorporated with the body of the tumor. All connections were now severed, save above and below, at which points it was found the tumor was continuous with a large nerve, the trunk of which above could be traced high up into the apex of the axilla, to the point where it is given off from the posterior cord of the brachial plexus. On irritating the trunk below the tumor those muscles responded which were supplied by the motor filaments of the musculo-spiral; this last fact was elicited by my friend Prof. Darby, and the same test was applied to all the nerves exposed, reserve ligatures on the trunk above and below previous to dividing the nerve itself, and the tumor was removed from its bed. The parts exposed were submitted to close inspection. One inch and a half of the axillary artery was exposed, points of origin of subscapular and dorsalis were plainly visible, the vein was not seen, the remaining nerves of the plexus appeared perfectly healthy, there was very trifling hemorrhage and no ligatures were required. Prof. Darby was kind enough to bring the edges of the wound together with his adaptation of the horse-hair suture, which appeared to answer admirably, and the part was left without further dressing. 21st.—Considerable tumefaction and discoloration of parts involved temperature in the fold of elbow on side of operation 100°, sound side 99°; much pain around shoulder parts below numb, both on radial and ulnar aspects of forearm. 22d.—Tumefaction less, numbness on ulnar side of forearm less; temperature, sound elbow 98°, operated side 99°.

This morning, the 27th, the temperature was the same on both sides; there had been no return of pain, and the numbness had very materially diminished.

The tumor was about the size of a small hen's egg. From a naked-eye inspection it appeared to have grown in the connective tissue between the bundle of nerves. The individual filaments were spread out over the surface, but more on one side than the other; the cut surface was yellowish and very succulent, the watery portions escaping freely on section; and there were two or three small cavities that looked more like spaces formed by extravasation than true cysts.

Appended is a note from Prof. J. W. S. Arnold, who

has been kind enough to make a microscopic examination of the tumor.

UNIVERSITY OF THE CITY OF NEW YORK,
MEDICAL DEPARTMENT.

No. 410 East 26th St.,
New York, October 27th, 1875.

MY DEAR DOCTOR:—The tumor is a myxoma, which has evidently taken the place of the nerve substance, for the tissue of the nerve can be traced to the capsule of the tumor, one portion of the nerve ending at the capsule, the other continuing its course from the capsule. The new growth has just replaced that portion of the nerve which corresponds to the diameter of the tumor. The substance which could be squeezed out from the cut surface gives the reactions of "mucin," and the round and stellate cells with gelatinous intervening substance point to the form of new formation called myxoma. The cuts are not yet dry enough to transport, but in a day or two I will send you one.

Sincerely your friend,

ARNOLD.

Dr. C. K. Briddon.

Remarks.—In the month of November, 1859, by invitation I operated at Prof. Willard Parker's clinic for the removal of a tumor of a somewhat similar character; in that case the ulnar was involved, and to about the same extent as in the present. Examined microscopically by Dr. W. H. Draper, it was found to be constituted of fibro-plastic nuclei cells and fibres, the nuclei and cells being more numerous than is usual in neuromatous tumors. The fibrous element generally predominated; there were no evidences of change in the imbedded nerve structure; it was classed amongst the fibro-sarcomas. Within a year the disease recurred in the form of a large fungating mass, that involved all the adjacent structure. Amputation at the shoulder joint was made; it recurred again in the bulbous extremities of the truncated nerve, which were excised. It however returned again when the patient entered the New York Hospital, where the scapula and one-half the clavicle were removed by Dr. Gurdon Buck. It was all of no avail, for the disease made its last appearance in the thoracic walls, and the patient died in St. Luke's Hospital.

Dr. Briddon also exhibited calculi, removed by operation of lithotomy from a gentleman aged 69 years, who had been the subject of prostatic enlargement. The preference was given to lithotomy on account of the irritable condition of the bladder, the introduction of an instrument for lithotomy being always followed by chills. The only feature of interest was the fact, that twenty-four hours after the operation the bladder became distended half-way between the pubes and umbilicus by a solid coagulum of blood. This probably had its origin from the prostatic plexus, and there was considerable difficulty in breaking it up. Subsequent to that his recovery was all that could be expected.

Dr. B. also presented another specimen of epithelioma of the upper lip, removed by operation from a patient aged 60 years.

The Society then went into executive session.

RUSSIAN MIDWIVES.—Amongst the women who this year follow the courses appropriated to their sex in the Medico Chirurgical Academy of St. Petersburg, the *Novoste* speaks of two peasant women (*sisters*), who were originally midwives at Tambow. When they made up their minds to enter the Academy, they set to work with the greatest zeal to acquire knowledge of the subjects necessary for them to pass their examination. They worked for two years without any extraneous help whatever, so as to be able to pass this ordeal, and further testified to their strength of will by making the journey from Schazh to St. Petersburg on foot.

Correspondence.

TREATMENT OF HYPERPYREXIA BY COLD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—You have recently published several articles upon the use of the bath in the treatment of hyperpyretic diseases, and naturally of the thermometer as a test of said treatment. These communications show that the profession is thoroughly aroused to the importance of the subject, and that THE NEW YORK MEDICAL RECORD is the leader of progress in that direction. This reminds me that in its first year (1867), THE MEDICAL RECORD published already a monograph, quoted by Wunderlich (in Sydenham ed., p. 42) as having spread the knowledge and love of these questions in America; and I need not say that since you have not ceased to publish valuable papers on these topics (the last ones from Dr. W. H. Thomson). It is not therefore to the paper that the following criticism is addressed, but to some of its correspondents, who exhibit their views, and their often valuable ideas, without the least regard for the history and bibliography of their subject; so much so, that writing for THE NEW YORK MEDICAL RECORD they commit—I hope unaware—the gross breach of courtesy of ignoring the publications so easily found in your excellent yearly index. This procedure of *forgetting one way what they want to teach another*, makes said correspondents lose much time, and the readers much more. If this criticism looks too broad to touch anybody, let us make it more pointed.

When the book of Wilson Fox, on the *Treatment of Hyperpyrexia*, came here in the beginning of 1872, the writer of the present paper gave, in THE NEW YORK MEDICAL RECORD, a note which contains all that has been since said—and a little more—on the substitution of bathing-dresses for bathing-tubs. This note was not sent for self-glorification, but *in memoriam* of a worthy man, and to retribute to him the honor of his invention (see in NEW YORK MEDICAL RECORD, March 15, 1872, *Treatment of Hyperpyrexia*). The same sense of justice prompts the same writer to-day to represent *de novo* the rights of Mathias Mayor to the invention of the portable bathing apparatus, which is the very thing most needed to give to thermography its most practical and mathematical instrument.

Mathias Mayor invented, about 1830, a bathing-dress composed of a thick flannel covered with oil-cloth (later india-rubber), both forming a continuous suite which completely enrobes the patient, and not less completely leaves him the freedom of his movements. This apparel was for years applied in the great hospital of Lausanne to the exclusion of bath-tubs, and was, with the wire-splints, the cotton instead of lint, Mayor's system of *déligation*, one of the features which attracted in Lausanne, Lisfranc, Sir Astley Cooper, and all the live surgeons of that period.

It is this Mathias Mayor's bathing-dress which I proposed, in THE NEW YORK MEDICAL RECORD of March 15, 1872, to revive, and to apply with some modifications to the purposes of our more recent practice of thermotherapy; insisting upon the morality of keeping this valuable invention under the name of its true inventor.

The modifications then proposed in THE MEDICAL RECORD were as follows: To establish, a little higher than the patient's bed or seat, a reservoir, with a glass rib and thermometer inserted, wherefrom the water

medicated or not, warm or frigid, but at measured temperatures, would run in the bathing-dress and inundate the patient. To likewise establish below a covered recipient, where the water could run from the hands and feet of the patient through pipes commanded by faucets, so that it could be kept or allowed to stream along his body, and also to prevent any emanation of contagious effluvia.

In this dress and in this bath the patient unable to move could remain for hours, for days if need be, reading, conversing, eating, sleeping, etc., and the patient who wants exercise may go about (with an ordinary over-aid) in rooms, wards, gardens, in a carriage, even on horseback—as the great Swiss surgeon was doing when called at a distance—using the opportunity of a ride in his hilly neighborhood to take his own *bain sans bainoire*.

Let this be taken from Mathias Mayor, as was his wire-apparatus for fracture, and many other of his inventions, and what becomes of the sacredness of authorship among physicians? Let us say more, if possible: What becomes of the tradition of our art, if anybody can rehearse a primary idea as their own, till it becomes as insipid as the quid of a regiment. Those who know the tradition of the treatment of hyperpyrexia, from James Currie to this day, have no excuse to offer for the substitution of their own name for historical names; and those who do not know, have abundant opportunities to learn.

E. S.

CONTAGIOUSNESS OF SCARLATINA.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In the fall of 1874 there occurred in this community a sporadic case of scarlatina, the origin of which I have been unable to trace, though the subject of the attack had been from home. I could not learn that he had been in any way exposed to any infectious influence. His attack was quite severe, but regular—acute nephritis following—from which he made perfect recovery. He was living at the time with a relative about one-half mile from his father's. After recovering from the attack, three months from the beginning having intervened, a new suit of clothes was brought him from home; not a single article of his apparel had he worn before; he was dressed in it, and having had a thorough washing he returned home. The first night he slept with a younger brother, who four days after was seized with scarlet fever, and subsequently four remaining children were attacked, in periods varying from four to eight days from his first return home. This ended the visitation of the disease in this part of the town, but at the same time another case appeared in another family about two miles from this case. There had been no communication between these families, they being strangers. It occurred in the person of a child of five years. He died at the fourth day. I afterwards learned that an older brother had returned home, having been living in a family sixty miles away, in which there had been three cases of scarlet fever, though he had not had the disease. This occurred in January of the present year.

The town was free from the disease until, about six weeks ago, there appeared suddenly in our midst, and within ten days of each other, thirty-five cases. It occurred to me that it could not be otherwise than interesting to trace out its origin, and follow its track, which at first seemed very mysterious, but soon shone out in light marvellously clear, though it has taken a good deal of inquiry and work to bring it into focus.

A female aged 14 years, returned home from a factory, had a severe sore throat; no eruption; each member of the family had the same affection, in the same manner. No physician was called, and the nature of the affection remained unknown. A little girl of eight years, belonging to a district school, called at the home of the sick ones and remained an hour; returned to school, and continued to go to school for the next three days, when suddenly she sickened with what proved to be scarlet fever, with eruption and sore throat; some six more fell sick from the same school on the following day, and within ten days in the neighborhood fifteen lay ill.

It next jumped the space of four miles, and appeared in another family, in which were four children, all of whom became sick. These were infected by a visit from the same girl who returned home with the sore throat.

The next appearance was in our village, which was about a mile from the other cases. It was in the person of an adult female, who spent an evening in company with a sister of the first one attacked, and who had also had a simple sore throat. This patient had a diphtheritic-looking throat, a membrane, tough and of yellowish white appearance, coming off on the eighth day. The eruption was characteristic, but irregular. Death occurred on the eleventh day.

From this last one eleven became directly infected, some having it in a mild form, and one having it in the malignant form and dying on the third day.

Now the centres of contagion or infection become so numerous, the interest of tracing ceases.

From these cases we draw the following conclusions: First, it is barely possible the disease may have arisen once independently, though this is doubtful.

Second, an unaffected person may be the carrier of the poison over a distance of many miles.

And, thirdly, the character of the disease is not determined by the peculiar feature of the disease from which one may become infected, but rather by some existing condition in the person attacked.

DAVID DANA SPEAR, M.D.

FREEMONT, October 19, 1875.

A SIMPLE TREATMENT FOR CLUB-FOOT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The following case may, perhaps, be of interest to your many readers, in showing what can be done in club-foot without the use of Scarpa's or Sayre's shoes, or other costly appliances that cannot be obtained by the poorer classes.

John K., aged seventeen months, had complete talipes of both feet, the variety being equino-varus. September 5th, I operated, dividing the tendo Achillis subcutaneously, and found that the foot could be placed in its natural position. The support was given to the parts by two pieces of lint to fit the bottom and outside of the foot, and the back and outside of the leg up to the upper fourth, joining the foot-piece at an angle of about one hundred degrees. These were well padded, and the heel was brought down into the angle formed by the foot and leg-piece by a many-tail bandage brought over the instep; then the roller was applied.

The feet were dressed each day, and an emollient lotion applied, and now at five weeks after the operation, when the boy is placed upon his feet, they retain their normal position, and the progress they have made from week to week makes me confident of a permanent cure.

J. B. TODD, M.D.

PARISH, N. Y., October 18th, 1875.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Nov. 7th, 1875, to Nov. 13th, 1875.

STERNBERG, GEO. M., Assistant Surgeon.—Granted leave of absence, on surgeon's certificate of disability, for six months, from Nov. 1, 1875, with permission to go beyond sea. S. O. 227, A. G. O., Nov. 9, 1875.

WILLIAMS, J. W., Assistant Surgeon.—Leave of absence extended one month, with permission to apply at Headquarters of the Army for a further extension of one month. S. O. 113, Military Division of the Missouri, Nov. 5, 1875.

KOERPER, E. A., Assistant Surgeon.—Ordered before the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to report in person to the Commanding General, Department of the Platte, for assignment to duty. S. O. 226, A. G. O., Nov. 8, 1875.

O'REILLY, R. M., Assistant Surgeon.—Assigned to duty at Fort Ontario, N. Y., as Post Surgeon. S. O. 227, Military Division of the Atlantic, Nov. 12, 1875.

HEIZMANN, C. L., Assistant Surgeon.—To report to the Commanding General, Military Division of the Atlantic, for assignment to duty. S. O. 226, c. s., A. G. O.

WHITE, R. H., Assistant Surgeon.—Relieved from duty in Military Division of the Atlantic, and to report to the Commanding General, Department of Texas, for assignment to duty. S. O. 226, c. s., A. G. O.

KING, J. H. T., Assistant Surgeon.—Ordered before the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to report to the Commanding General, Department of Texas, for assignment to duty. S. O. 226, c. s., A. G. O.

HALL, J. D., Assistant Surgeon.—To report to the Commanding General, Military Division of the Atlantic, for assignment to duty. S. O. 226, c. s., A. G. O.

COWDREY, S. G., Assistant Surgeon.—To accompany 5th Regiment of Artillery to the Department of the Gulf, and, on arrival there, report by letter to the Commanding General of that Department for assignment to duty. S. O. 226, c. s., A. G. O.

HALE, W. R., Assistant Surgeon.—Relieved from duty in the Military Division of the Atlantic, and to report to the Commanding General, Department of the Columbia, for assignment to duty. S. O. 226, c. s., A. G. O.

TORNEY, G. H., Assistant Surgeon.—To accompany 5th Regiment of Artillery to Department of the Gulf, and, upon arrival there, report by letter to the Commanding General of that Department for assignment to duty. S. O. 226, c. s., A. G. O.

CRAMPTON, L. W., Assistant Surgeon.—Assigned to duty at Natchitoches, La. S. O. 198, Department of the Gulf, Nov. 4, 1875.

ROSSON, R. L., Assistant Surgeon.—Relieved from duty in Military Division of the Atlantic, and to report to the Commanding Officer, Department of Arizona, for assignment to duty. S. O. 226, c. s., A. G. O.

Medical Items and News.

DR. JOHN HUGHES BENNET.—*The British Medical Journal* of October 9, in an obituary notice of this eminent man, gives a list of one hundred and five papers, addresses, etc., written by him, together with the titles of six works of greater magnitude; and in summing up the results of his arduous life, enumerates the following as being his chief contributions to the science and practice of his profession:

1. He was the principal agent in advocating the use of cod-liver oil in this country, in the treatment of tubercular diseases.

2. He was the first systematically and practically to teach histology and the use of the microscope.

3. He was the first to introduce the systematic teaching of clinical medicine, with the aid of all the modern appliances now in use.

4. He was the first to show the great importance of the microscopical examinations of diseased organs, and more especially of the great nervous centres.

5. He pointed out the errors in the prevalent method of treating acute inflammations of internal organs, and more especially of the lungs; and was highly instrumental in leading to the almost entire abolition of bleeding in these affections.

6. He condemned the indiscriminate drugging of patients much in vogue, and especially the too free use of mercury in syphilitis and in diseases of the liver.

7. He was the first to record a case of leucocythæmia, and while he did not at the time discern its true character, he contributed largely to its diagnosis and pathology, and also to the application of the discovery to an explanation of the functions of the lymphatic and blood glands.

8. He was one of the first to advocate combined labor in the prosecution of scientific inquiries, and to the principle of grants of money being given by public bodies for that purpose.

9. He contributed to physiology his well-known molecular theory of organization, which, if not adopted generally, has at all events led to a reconsideration of the question by the upholders of the cell-theory, and to considerable modifications in their views.

EIGHTH ANNUAL REPORT OF THE BOARD OF HEALTH OF THE CITY OF ST. LOUIS.—The report shows a remarkably low death rate of 14.45 per 1,000 in a population of 450,000, and, besides the usual statistics, has interesting reports by the clerk, health officer, city chemist, and the officers in charge of the city institutions. According to the report of the health officer, St. Louis has over one hundred and sixty miles of sewers, which have cost, including private sewers, which are about fifty miles in extent, over \$6,000,000. The water-works of the city supply 19,500,000 gallons per diem, a daily consumption of 3,000,000 gallons over last year. Philadelphia is the only American city of size which has a smaller average number of residents to each house. The city chemist reports upon the condition of well and cistern water, ice, filters, beer, meat, bread, cider, vinegar and pickles, milk, etc.

M. LORAIN, Professor of Medical History to the Faculty of Medicine in Paris, is deceased. M. Lorain, who was only fifty years of age, died very suddenly of what is believed to have been an attack of meningeal apoplexy. He succeeded the late M. Darenberg in the professorship about two years ago.

SMALL versus LARGE MATERNITIES.—After a lengthened discussion the following conclusions were arrived at by the Obstetric Section of the International Congress of Medical Science:

1. Urgency of a radical reform in the system of assistance rendered to lying-in women.
2. Complete abandonment of large maternities.
3. Replacing of large maternities by small houses with separate rooms for the object of midwifery instruction.
4. Creation of a house of reserve in the vicinity of the maternity, with separate medical attendants, etc.
5. Extension, as much as possible, of assistance of all kinds to pregnant and lying-in women at their own houses.
6. That accouchements at the residences of midwives, at the expense and under the *surveillance* of the charitable institutions, present the means of gradually suppressing maternities. This measure, desirable at all times, becomes a necessity in time of epidemic.

INSTITUTE FOR RACHITIC CHILDREN AT MILAN.—Dr. Pini, of Milan, communicated to the International Congress of Medical Science that, with the assistance of the charitable public, he had founded a hospital, or rather school, where he receives, during the day only, children suffering from rickets. He gives them, besides suitable medical treatment, wholesome and strengthening food, makes them practise gymnastics, and returns them to their family in the evening. By this method he states that he has obtained the most satisfactory results.

THE ARSENIC EATERS of Upper and Middle Syria, according to Dr. Knapp, have discovered that arsenical food has very much to justify it, and that taken in reasonable quantities it is a very slow poison. They assign as their motives for indulging in the habit that it prevents illness, furthers their wish to look rosy and healthy, that it is a remedy against difficulty of breathing, and assists the digestion of indigestible food.

A poacher told Dr. Knapp that he acquired courage by the habit. The appearance of the arsenic-eaters in all cases known to him is healthy and robust. He thinks only robust persons can become accustomed to the practice. Some of them attain a great age. Thus in Neiring he saw a charcoal-burner, upwards of seventy, still strong and hearty, who, he was told, had taken arsenic more than forty years, and he heard, too, of a chamois hunter of eighty-one, who had long been used to eat arsenic. The dose is, of course, very small at first, and is gradually increased, the largest quantity eaten in his presence by the poacher in Neiring being fourteen grammes. A certain Matthew Schober, in Ligist, ate seven and a half grammes before Dr. Knapp, on the 17th of April, 1865. The intervals, too, at which arsenic is taken vary—every fortnight, every week, twice or three times a week.

THE ACADEMY OF MEDICINE OF PARIS has recently received two legacies which will materially aid the progress of scientific medicine in France. M. Desportes left to the Academy thirty thousand francs, the interest of which is to supply an annual prize for the best memoir on a therapeutical subject to be chosen by the Academy. M. Demarquay left to the Academy the sum of one hundred thousand francs towards the erection of a building for its use, worthy of the position the Academy has obtained. In case the cost of erection of such building is defrayed by the Government, the interest of the legacy is to be devoted to the establishment of an annual prize, the subject of which is to be decided by the Academy. M. Demarquay has also

left a legacy to the "Association Générale de Médecine de France."

ESERINE DISCS IN TIC.—Dr. Munro, in a note to *The Lancet* of Sept. 25th, describes a new and agreeable excipient for the administration of eserine (physostigmine), the active principle of Calabar bean. He finds that one twenty-fifth of a kilogramme (.0006 grain), when put up in gelatine squares or discs, answers the purpose, one-half removing the tic, if it has no persistent cause, in from five to fifteen minutes. The discs are made by Duquesnel, of Paris. Dr. M. also finds that the bean, in the form of the extract, is of advantage in incipient bronchitis, congestion of the liver, and phthisis with hot, dry skin; in sufficient doses, which for an adult are at least from one-fifth to one-sixth grain, he finds the temperature reduced from two to three degrees, the dose being repeated every four or six hours, under careful watching, until the desired effect is produced.

COMPULSORY SERVICE OF FRENCH MEDICAL CADETS.—A good many French naval medical cadets (*aidés médicaux de la marine*) have, it seems, tendered their resignations after obtaining the degree of doctor, with a view of entering upon medical practice. This is contrary to an engagement which they sign on entering the navy, to serve for ten years after obtaining the degree of doctor.

Admiral Montaignac has issued an order announcing that in future such resignations will not be accepted. A late Board of Admiralty had prepared a similar scheme of naval medical cadetships for the English marine service, with a like view to insuring the bondage of naval medical officers during a fixed period, however unpalatable the service might be; but the interference of the medical journals and societies prevented this scheme being put into force.

LOUISE LATEAU.—The latest intelligence concerning Louise Lateau, the so-called mystic of the Bois d'Haine, is that she no longer bleeds, and that her stigmata have disappeared since one of her sisters has taken up her abode with her and resolutely closed the door against all visitors.

The *Presse Belge* adds that Louise Lateau, who, according to the Roman Catholic journals, took no food whatsoever, now displays a remarkably good appetite.

Dr. Sibson has been requested to deliver the first of the newly instituted annual series of Harveian Lectures of the Harveian Society of London. He has selected as his subject "Bright's Disease and its Treatment, considered mainly in Relation with Arterial Tension from Blood-Contamination." The lectures will be delivered on December 2d and 16th.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

[THE MEDICAL RECORD is published every Saturday. Notices of meetings, lectures, operations, etc., intended for publication in this bulletin should be received at the office, 27 Great Jones Street, one week previous, to insure their appearance.]

Wednesday, Nov. 24.—N. Y. Pathological Society, at the College of Phys. & Surg., cor. 23d st. and Fourth av.

Thursday, Nov. 25.—N. Y. Medico-Legal Society, at the College of Phys. & Surg., 23d st., cor. Fourth av.

Friday, Nov. 26.—N. Y. Medical Journal Assoc., No. 12 W. 31st st.

Original Communication.

A NEW METHOD OF CONTROLLING THE VELUM PALATI AND ENLARGING THE PHARYNGO-BUCCAL APERTURE IN RHINOSCOPIC EXPLORATION.

By PHILIP S. WALES, M.D.,

MEDICAL INSPECTOR U. S. NAVY.

THE difficulties in the way of thoroughly illuminating and examining the naso-pharyngeal cavities are well known to all practical workers with the rhinoscopic mirror. The variations in the area of the space bounded in front by the velum palati, and behind by the posterior wall of the pharynx, are wide in the normal condition. In certain subjects it is so ample, that at the first "sitting," most of the parts situated above the level of the palatal process, without the aid of any mechanical contrivances, may be easily inspected with a large mirror. In by far the greater number of persons, however, this area is more restricted, even narrowed to a very small fissure; in either case the smallest mirror only being available, and some mechanical contrivance required to enlarge it. This condition offers two difficulties, that must be overcome to arrive at success; it cuts off the necessary degree of light indispensable for thoroughly viewing the parts, and precludes the use of mirrors of sufficient size to make an accurate examination of the relative condition and position of the parts. The irritability of the palate and fauces also varies in different persons, occasionally being so trifling that the velum will remain relaxed and hang down well in front of the pharyngeal wall, as it does normally in respiration through the nostrils, and in consequence good observations may be made. In some of these cases even the touching of the velum with the mirror does not excite it to contraction, which, however it ought never to be permitted to do. Most generally the irritability is such that upon the mere opening of the mouth, or a glance of the eye of the patient at the operator's hand holding the mirror as it approaches his face, will instantly cause irresistible contraction of the palatal veil upwards and backwards, against or nearly in contact with the pharynx.

The half arches vary in amplitude and shape. The space bounded by these and the base of the tongue presents occasionally almost a quadrilateral outline and are widely separated, but usually the space is irregularly triangular, the apex of the triangle corresponding with the uvula, while its base is narrow. These conditions correspond with similar ones of the base of the inferior dental arch. The age of the patient also affects the amplitude of the fauces, being proportionally smaller, the younger the patient is inside of adult age.

The base of the tongue is subject to various peculiarities of size, shape, and degree of elevation. In a few, mostly adult individuals, it is broad and flat, and when the mouth is widely opened lies well down below the plane, corresponding to the border of the molar alveoli. This position of the tongue is taken immediately the jaws are separated, or may be assumed by the voluntary efforts of the patient. In a still larger proportion of adults and in most children this part of the tongue is narrower, thick from above downwards, and when the mouth is open rises above the plane of the crowns of the molars and often completely hides the entirety of the velum from view,

touching even the posterior portion of the palatal process.

Many persons, especially those of nervous temperament, have such imperfect volitional control over the movements of the tongue, that even when all the physical conditions of conformation are favorable, and but little irritability exists, the rhinoscopic examination is very difficult. The tongue persistently rises to the roof of the mouth and offers considerable resistance to the spatula, the use of which not unfrequently produces under these circumstances repeated retching.

The first attempts to inspect the naso-pharyngeal region were made by Czernak during the winter of 1857-8, and the method then adopted he called rhinoscopy. It was first tried upon himself with the aid of his auto-laryngoscopic apparatus, and by frequent practice he saw very distinctly a portion of the nasal fosse, the septum, the turbinate bones, the posterior surface of the velum, and the orifices of the Eustachian tubes. In examining other persons, he made them depress their tongues themselves by means of a tongue depressor; the velum then became readily accessible, and when wanted, he elevated and drew it forward with a hook, so as to facilitate the introduction of the mirror. Manipulation in this manner required both hands,—one in holding the hook, and the other the mirror. In order not to occupy the two hands simultaneously, he had made at the commencement of his rhinoscopic studies, a small instrument, which might serve at the same time the purposes of a hook and a mirror, and which would necessitate the employment of one hand only. He describes it as constructed out of a metallic tube, bent at a right angle, and therefore composed of two arms, of which one is long, whilst the other—the vertical—is short; an oval steel mirror is attached at an angle of forty-five degrees, at the bent part, between the two arms. The light enters through the long arm; the short arm is obliquely cut at its extremity, to be introduced behind the velum into the pharyngo-nasal cavity. He was soon convinced of the necessity, he tells us, of substituting for the major part of the long arm a half tube, in order to have more light, and a more close inspection of the small oval mirror. It seemed to him equally advantageous to replace the short arm by a vertical plate of metal, which could be secured and removed by means of a ring; the introduction of the instrument was thus facilitated. He goes on to state that this simple, and it may be said primitive instrument, he frequently employed with success upon himself firstly, and afterwards upon patients. The position and inclination of the apparatus are the determining cause, by means of which some parts of the pharyngo-nasal cavity and of the nasal fosse, rather than others, are found illuminated and reflected by the mirror. In July, 1859, he made some rhinoscopic experiments upon a dead body, for the purpose of more readily exposing those regions, till then inaccessible to view, and for the better appreciation of the bearing of his new method of exploration. These experiments again convinced him, that in this way we can expose to view the posterior wall of the velum, the walls of the pharyngo-nasal cavity up to the sphenoid bone, the orifices of the Eustachian tubes, and the extent of the posterior orifices of the nasal cavity, as well as the turbinated bones. *He did not perceive the floor of the nasal cavity, nor of the inferior meatus; but he suggested that it might be done by using double mirrors, of which the superior might reflect its object into the inferior.* The utility of this suggestion has not been made apparent. In comparing the relative difficulties of rhinoscopic and laryngoscopic

inspection, he declares that those of the former are much graver than those of the latter, unless favored, for example, by insensibility, by fissure or partial deficiency of the velum. Czermak's rhinoscopic instrument described above, does not seem to have been a success, and was laid aside; for in March, 1860, he examined a case in which there was some pharyngeal disease. The anatomical conditions, he states, were favorable, and an inspection was first made without any instrument to control palatal movements, but in order to examine the affected parts with greater liberty, and on a more extensive scale, he requested the patient himself to depress the base of his tongue with a rectangular spatula; and then, he says, with his left hand he elevated the velum palati in front and above, by means of a flat hook with a long stem, assuming the form of a spatula, of which the flat part contained an opening. In his article two spatulas are figured, one with and one without a fenestrum. The application of this hook, he remarks, did not cause the slightest inconvenience in the present instance; and after regulating the inclination and position of the mirror, which had been introduced into the pharynx with his right hand, he was enabled to complete, by degrees, a satisfactory and clear examination of the part affected, which permitted him to make a drawing that figures in his paper, showing the extent and character of the disease. With the aid of the spatula he did not see the whole of the posterior nares; for he distinctly states that on the right side, which was normal, "we can perceive through the posterior orifice of the nasal fossa of the same side a portion of the upper part of the turbinate bones, and a portion of the meatus of the right side, whilst the inferior parts are hidden by the velum palati."

That Czermak was fully impressed with the difficulties encountered in this and many other cases in thoroughly and completely exploring the nares and pharynx, in consequence of the movements of the velum, and that he entertained strong hopes that instruments would be devised, or aid of some kind afforded finally by zealous laborers in this field, is manifest in a concluding paragraph of his paper, where he states that "it is only in the future, when the impulse which I have given to the subject shall have been followed for some time, that we can attempt to judge to what point the local depression of sensibility by means of cold water, of anaesthetics, narcotics, or the patients getting used to it, on the one hand, and the gradual increase in the powers of dexterity of the physician on the other, may facilitate the use of the rhinoscopic method, if not favored by circumstances."

This is the point at which, in 1860, Czermak left the subject. He had not devised a practical means to overcome the muscular action of the velum palati, and therefore had not seen, except in glimpses, the entire walls of the naso-pharyngeal cavities as far as anatomy of the parts permit.

Moura wrote four years later, that "all authors have recognized the necessity of enlarging the inferior orifice of the pharyngo-nasal cavity, although we may sometimes make a rhinoscopic examination without interference from this part." That this necessity was still deeply felt, is shown by the multiplicity of suggestions and the array of mechanical devices for controlling the palatal movements, described by the writers alluded to. To render the palate flaccid, it was proposed to submit it to repeated touching and rubbing to diminish its sensibility, to spray it with bromide of potassium (Auzias-Turenne), to weary the patient out and to distract his attention. Voltolini hoped by forcibly depressing the base of the tongue, Semeleder by directing the patient to breathe through

the nose, and Czermak to cause him to emit nasal sounds, to relax the palatal muscles, so as to give sufficient space for the use of the mirror. All these various plans may occasionally succeed, but for the art of rhinoscopy to make any considerable progress, more efficient means are required. That they were practically of little account, may be easily conceived when it is known that the most successful operators were constantly devising mechanical contrivances.

Türk constructed an instrument like a polypus forceps, for seizing the uvula and drawing forward the palate—one similar to the urethral forceps for clamping the uvula, a small tube with wire sling to catch the uvula, and lastly an instrument like a lithotrite fixed by a screw. Moura suggested his *tenneur du voile du palais*, which was simply two hooks sliding one upon the other, and mounted upon a handle, and designed to seize the palate. All these various contrivances are useless, for experience has shown that we cannot by force pull forward the elevated palate. The same amount of irritation and energetic contractions as that excited by *seizing* the palate in order to pull it forward, is not noticed when palate hooks are employed. This sort of instrument was adopted by Czermak, and Türk also suggested a hook with a horizontal groove to prevent the velum slipping off. These instruments are much too heavy and irritating, and cannot, as a general rule, be borne by the patient, and the soft structures have not unfrequently been damaged by their use. To overcome these objections, I constructed some years ago a hook of flexible wire, which is light, easily managed, and can do no harm, and is capable of doing all that such an instrument can accomplish.

A third method may be attributed, I believe, to Türk, who used an instrument consisting of curved points which are introduced behind the velum and then opened; one blade rests on the posterior wall of the pharynx, while the other presses the velum forwards. Störk combined the hooks and mirror, and is described by Semeleder in the following manner:

Suppose a mirror and a hook, both having rings on their extremities, their handles, at the middle joint stems, are united like a pair of scissors, so that pressing together the separate rings, the hook lying upon the mirror is raised; the mirror together with its stem has a longitudinal sliding movement; whilst upon the anterior portion of the mirror stem a small leaf may be placed as a substitute for the tongue-spatula. The mirror and the hooks are pressed against each other by a spring. The instrument thus closed is introduced behind the velum, and then, by an approximation of the rings, opened, and the hook, upon which the velum now rests, is drawn towards the observer.

Voltolini's rhinoscope is a long, black spatula, on the end of which, at a prescribed angle, a steel mirror with a short neck is placed.

The above account of the instrumental and other means to control the movements of the palate is a fair summing up of what has been done in this direction, and as may have been gathered from its perusal, they are all more or less imperfect, difficult of management, and not of general application. In my opinion, the method which I shall now describe overcomes all the difficulties as far as the anatomical structure of the parts will permit, leaves nothing to be desired, and fully realizes Czermak's sanguine anticipations.

My principle consists essentially in overcoming the contraction of the palatal muscles by elastic force, and the means of fully carrying it out will be found in an india-rubber cord. The simplest method of

putting it in position after having selected one of such a diameter—two millimetres will do—as will readily pass through the inferior meatus into the pharynx without any instrumental assistance, is the following:

One end is introduced into each nostril, until they both reach the lower portions of the pharynx. At this moment the patient is directed to cough, if the presence of the thread has not already excited this movement; the force of expiration will pretty surely project them into the mouth, when they may be apprehended with the fingers and drawn externally until the middle portion of the cord, which is external, is arrested against the nasal septum. Gentle traction is continued until the soft palate is well drawn forward, when the threads are passed up over the ears, and downwards beneath the chin and there tied, or they may be held by the patient himself. At any moment after the ends of the elastic are secured at the point indicated, the tension of the cord and correlative palatal pressure may be increased by seizing the threads as they pass out of the mouth and gently drawing them forward, until the palatal contraction is entirely overcome, and the area of the pharyngo-buccal space ample enough to receive the largest mirror. It will sometimes be observed that where there is very much irritability, the velum palati momentarily contracts, especially at the time when the mirror is introduced, but soon yields to the elastic force of the thread. Should any impediment whatever exist in the nostrils, that the cord cannot be passed by itself, the little instrument I have described below works admirably as a cord carrier. Of course, an expert hand may make use of any instrument that may chance around a catheter, slips of whalebone, or wood. I have found the contrivance that passes under the name of Belloc's sound, put in some pocket-cases, is not in a majority of instances appropriate to effect this object: it is too large, and too much curved to pass through the nostrils without being propelled by an improper degree of force that causes both pain and bleeding. An example of these objections to that instrument as ordinarily furnished may be related. At a demonstration in my office, when six medical gentlemen were present, Belloc's sound was tried upon the nostrils of all present; it could not be passed except in a single case, and then but upon one side. The experiment, indeed, might have succeeded in all, but the instrument was not pressed when any considerable amount of pain was produced.

The device mentioned above is simple, cheap, and easily managed. It is a thin lamina of soft metal, six inches long and less than an eighth wide, mounted at each extremity with a small ring of an amplitude a little greater than the elastic cord, which having been passed through them, is tipped with small, smooth, oblong fragments of lead. When the instrument is to be used, the cord is drawn through the rings until one of its tips comes against the corresponding ring; slight tension of the elastic will retain the two in contact while the point thus formed is being conducted along the inferior meatus. When the metallic point reaches the posterior wall of the pharynx, the elastic projecting externally is pulled through the exterior ring, and made quite slack so that the instrument may be withdrawn from the nares, leaving the cord in position; a similar proceeding is then practised upon the other nostril.

The metallic points of the cord, now in the pharynx, may be easily thrown forward by coughing or hawking, and seized with the fingers and drawn externally. The metallic lamina, on account of its flexibility, will

thus be bent as a bow over the bridge of the nose, and out of the way. This is a neat, facile, and quick method of placing the elastic cord in the nostrils. I have also used in cases where there was obstruction to the passage of the cord, a catheter similar to the one designed for the Eustachian tube, except that both ends are alike; the catheter is introduced into one of the nostrils, and when its point is eligibly lodged posteriorly, the cord may be thrust through it until it reaches the throat and is expelled by the mouth by expiratory efforts, when the catheter may be withdrawn and the same manœuvre executed upon the other side. The cord tipped with a metallic point may also be carried into the pharynx by means of a little probe similar to the *porte-mèche*, the point of which is received into a depression on the tip. In the course of my experiments as to the best method of controlling the palatal contraction, I have used several other devices for conducting the elastic into position, but the methods described recommend themselves by their simplicity and general application. The cord should pass along the inferior meatus, which experience shows is oftencast free from those morbid changes which block up the area of the nostrils. The mucous membrane of the nose and throat is by far more tolerant of the contact of elastic substance than of metallic objects, and it is surprising how little indeed in many cases is the irritation caused when the soft palate is doubled upon itself and stretched forward by the cord. I have repeatedly kept it in this position for thirty and fifty minutes. The area gained varies, of course, with the normal size and configuration of the patient's fauces. I have within a few hours of the present writing expanded the area in one case—by no means favorable, for the throat is exceedingly irritable and narrow, and there is chronic pharyngitis—by gentle traction on the cord until the antero-posterior diameter measures one inch and a quarter, and the transverse one inch. With a seven-eighths mirror, the larger portion of his posterior nares can be seen at one view.

The discovery of means of amplification of the pharyngo-buccal aperture has occupied my attention for several years. I have had only moderate success until the discovery of the devices I now bring to the notice of the profession.

Its chief merits are the simplicity of the apparatus, and the facility with which any professional person may employ it in exploring the posterior nares and the pharyngeal cavity. The cord itself may well take the place of Belloc's sound in any case wherein it may be necessary to conduct a thread through the nostrils, as in plugging the nares for epistaxis. Here, however, I employ a little bulb of rubber at the end of a hollow rubber cord, and after the bulb is placed in position through the fauces, it may be inflated by blowing air through its open extremity which projects exteriorly from the nose.

DUMB RABIES.—Professor A. Liantard sends us, under date of November 11th, a memorandum of a case of so-called dumb rabies in a Danish slut, which was brought to the hospital of the American Veterinary College, and placed there under observation. She showed all the symptoms characteristic of the disease, viz., paralysis of the lower jaw, peculiar appearance and coloration of the tongue, characteristic barking, spasmodic contractions of the muscles of the body followed by loss of power in the hind extremities. Her temperature in the rectum ranged between 102.5° and 102.8°. At the request of the owner she was killed twenty-four hours after admission.

Original Lecture.

UROCYSTIC AND URETHRAL DISEASES OF WOMEN.

By ALEX. J. C. SKENE, M.D.,

PROFESSOR OF GYNÆCOLOGY IN THE LONG ISLAND COLLEGE HOSPITAL,
BROOKLYN, N. Y.

LECTURE I.

GENTLEMEN: You might naturally suppose, after what you have learned from the chair of General Surgery regarding diseases of the urinary organs, that anything more on the subject would be unnecessary. You remember, however, that what you have heard had special reference to the male, and it remains for me to tell you about the same and allied diseases in the female.

The anatomy and physiology of the bladder are the same in both sexes, but the relations of this organ differ in male and female; and circumstances affect them so as to make quite a difference in their pathology. This warrants my discussing this subject, and is the reason why I seemingly trespass on the surgical domain.

In works on anatomy the male bladder is taken as the standard, and accurately described, while little is said about the female bladder, except a passing notice of some points where it differs from that of the male. This organ is simply a sac or bag, the walls of which are composed of four coats—serous, muscular, areolar, and mucous. In this respect it resembles the alimentary and the urogenital canals. The external coat is the common covering of all the abdominal viscera-peritoneum. The muscular coat has two layers, a circular, and a longitudinal, so arranged as to insure uniform concentric contraction. Beneath the muscular coat is a layer of areolar tissue, which contains the principal blood-vessels and nerves, and is the bond of union between the muscular structure and mucous lining. The mucous membrane of the bladder is peculiarly wanting in glandular structures, other than simple mucous follicles and small racemose glands near its neck. The union of the mucous and muscular coats by the areolar tissue is somewhat loose, except at the triangular space at the base of the bladder, where they are more firmly connected. This triangle, known as the trigonum vesicæ, is bounded on each side by slightly elevated ridges, which terminate posteriorly at the points where the ureters enter the bladder. At the apex of the triangle, in front, there is another slight ridge just at the point of entrance of the urethra. The mucous membrane in the trigone is smooth, and thinner than the rest of the internal coat.

The bladder is triangular when empty, and ovoid when full. Its vertical diameter is longest in the child, but in the adult female it is longest from side to side. It is situated behind the pubes and in front of the uterus and vagina. It is separated from the uterus by the peritoneum, down to near the junction of the body and cervix uteri. From that part downward for about half an inch the bladder and uterus are held in contact by areolar tissue. The remaining portion of the posterior wall of the bladder rests upon the anterior vaginal wall, the two being very loosely united, except at the neck of the bladder, where the union is much more complete. This union with the

uterus and vagina posteriorly, and the pubes in front, holds the lower portion of the bladder in position. The upper and greater portion of this organ is held in place by a number of ligaments, five true and five false. The true ligaments comprise two anterior, two lateral, and the cord of the urachus, while the false ligaments, formed from folds of peritoneum, are two posterior, two lateral, and one superior.

The urethra is about an inch and a half in length, beginning at the neck of the bladder, and extending to the meatus urinarius. It is located in the upper portion of the pubic arch, and is imbedded in the anterior vaginal wall, its direction being downwards and forwards in a slight curve. It perforates the triangular ligament or deep perineal fascia, two layers of which extend around it, one forward, and the other backward. The diameter of the urethra is about a quarter of an inch; but, owing to the unresisting nature of the tissues surrounding it, can be dilated to a great extent. It is lined by mucous membrane, which is disposed in longitudinal folds, and is continuous internally with that of the bladder, and externally with that of the vulva; the mucous membrane is surrounded by a proper coat of elastic tissue, to which the muscular fibres of the detrusor urinae are attached. The meatus is encircled by a ring of fibrous tissue, which prevents it from distending with the same facility as the rest of the canal.

The function of the bladder is to act as a reservoir for the urine as it is secreted by the kidneys. As the urine flows very slowly but constantly from the ureters, the bladder distends to receive it. The bladder fills first in the posterior and lateral directions, until it meets resistance, when it extends upwards into the abdominal cavity. When the organ is filled to its capacity, or when the character of the urine is unnatural and irritating, then the desire to urinate comes on, and the contents are expelled. In other words, urination occurs. But the bladder is no sooner emptied than it begins to refill, and thus goes on unceasingly. The filling of the bladder is one of the involuntary actions which the subject is not conscious of. Urination is governed by reflex nerve action, and is partly voluntary and partly involuntary. When the conditions which call for evacuation are present, there is an impression made on the sensory nerves of the bladder, which intimation is conveyed to the brain, and then the muscles which effect urination are called into action, and the bladder is emptied by volition.

The number of times which the bladder is emptied, and the quantity of urine passed in twenty-four hours, vary considerably. The relative amount of elimination performed by the skin, the quantity and character of fluids taken, the amount of labor performed, all modify the quantity of urine secreted, and the quality of the urine and the irritability of the bladder influence the frequency of urination. But there are limits to these variations. If a person micturates more than nine times or less than twice in twenty-four hours, or passes more than forty-five or less than twenty ounces in the same period, that would be beyond the limits of health. In a healthy condition the desire to urinate is rarely so urgent but it can be resisted for a time without great distress, and during an ordinary period of sleep the urine can be retained without inconvenience.

With these few statements to recall to your minds some of the important points in the anatomy and physiology of the bladder, we now come to the discussion of some of the more important functional and organic diseases of this organ.

Cystitis is one of the most distressing diseases which

any one can have, and it is by no means of rare occurrence. Women suffer more frequently than men, I believe. Unfortunately it is a complaint difficult to manage by any known form of treatment. We are not able at all times to cure cystitis, and, what is worse, we sometimes fail to completely relieve the pain and suffering caused by this affection.

Acute cystitis occurs occasionally, but is rare compared with the subacute form, and unless recovery is prompt the disease tends to assume the chronic condition.

The morbid anatomy of acute cystitis is the same as in acute inflammation of mucous membrane in other parts of the body. The membrane is swollen and relaxed, florid with congestion, and usually covered with mucus. There is exfoliation of the epithelium, as shown by the partially denuded condition of the membrane, and the presence of pus and old cells in the mucus passed with the urine.

Chronic cystitis is generally catarrhal, and in the earlier stages of the disease the mucous membrane is swollen and thickened. In place of the redness of acute inflammation, the membrane becomes of a muddy gray color, and is covered with a dark or yellow muco-purulent secretion. As the disease advances there is excessive cell-growth on the free mucous surfaces; patches of ulceration appear here and there, attended with the formation of pus, and these spots bleed occasionally. The ulceration is very extensive in some cases, and then the membrane is quite red, and looks like a granulating sore. The more advanced tissue-changes which occur in the male bladder, such as eccentric and concentric hypertrophy in a marked degree, and submucous abscesses, do not occur as often in the female. The decomposed urine mixed with pus, mucus, blood, and shreds of membrane, which form the chocolate-colored fluid found in the advanced stages of the disease in the male, are rather rare in women. In cases of long standing the vesical ends of the ureters are obstructed by swelling and hypertrophy of the walls of the bladder. This produces obstruction to the free flow of the urine, and leads to dilatation of the ureter and pelvis of the kidney, and in some cases organic renal disease follows in the train of pathological sequences.

In some text-books you will find three forms of cystitis described: cystitis mucosa—catarrh of the bladder; interstitial cystitis; and pericystitis, or epicystitis. As a rule, the last two forms are consequences of the first, and I prefer to class all the pathological conditions under the one head—cystitis. What is said in this connection will have reference to the catarrhal form, including ulceration.

The symptoms of cystitis are chiefly manifested by deranged function of the organ. The disease does not, at the beginning, affect the general system so as to produce marked disturbance. There may be some slight febrile symptoms in the acute form, but in the subacute, and by far the most frequent form, the general health is not affected, except by debility caused by the pain and want of sleep. When the disease advances to destructive organic change in the bladder,—in short, when vesical phthisis occurs—we get all the constitutional symptoms of phthisis. In cases of long standing, which are complicated with inflammation of the pelvic organs, or organic renal disease, the constitutional symptoms are such as occur in these respective troubles.

The chief and only positive symptoms are the derangement of the function of the bladder, changes in the character of the urine, frequent and often painful urination, and vesical tenesmus. These symp-

oms vary in severity according to the extent of the cystitis. In the mildest form of the trouble there is a frequent desire to pass water, which often comes with unusual force. Micturition is followed by a desire to strain, as if the bladder had not been emptied. This feeling subsides partially, or wholly, after a time, and returns again after each act of urination. As the disease advances, and in the more marked degrees of the trouble, all these symptoms are more severe. The least drop of urine in the bladder tortures the patient until it is passed, some being obliged to urinate every ten, fifteen, or twenty minutes, night and day. In fact, the desire to urinate is constant, and when the bladder is emptied the painful tenesmus is very severe. Sometimes, when the bladder contracts completely together, it causes very sharp, stinging pain.

The changes in the urine are valuable aids to diagnosis. In the majority of cases the urine is strongly alkaline, but in some it is constantly acid. At the beginning of the disease the urine contains a small quantity of mucus, which soon increases, rendering the urine turbid and darker in color. The deposit, at first transparent, becomes thick, opaque, and of a gray or yellowish color. In addition to the free admixture of mucus, exfoliated broken-down epithelium and pus are found in less or greater quantity, and finally, blood is present from time to time. When there is a large quantity of pus, and the urine is strongly ammoniacal, the deposit becomes converted into a thick, tenacious, jelly-like mass, as coherent as half-liquid glue. This effect is said by some to arise from the action of alkaline urine on the pus and mucus, by a process of fermentation. Others claim that the fermentation is not caused by the urine, but is due to the presence of low organisms, such as vibriones and fungi. Be this as it may, this peculiarropy mass in the urine occurs only in advanced chronic cystitis.

The diagnosis of cystitis is generally easy in marked cases, but in mild attacks care is necessary to distinguish it from other conditions which cause similar symptoms. Frequent urination occurs in many other troubles, such as prolapsus uteri, adhesions from pelvic peritonitis, abdominal tumors, and in the various neuroses. Pregnancy almost invariably gives rise to annoying frequency of micturition.

Frequent urination from prolapsus is worst when the patient is standing or walking, and is relieved, either wholly or to a great extent, by the recumbent position, while in cystitis position makes no marked difference.* In adhesions from pelvic peritonitis, abdominal tumors, and pregnancy, the desire to urinate only comes on when the bladder is partly full, and is about the same night and day. Frequency of urination is not usually accompanied with tenesmus, except when due to cystitis. In the various forms of neuroses of the bladder the frequent urination is very irregular, the patient at times being almost entirely free from it, and at other times troubled very much.

The frequent and painful urination of cystitis may be simulated by urethritis, and other painful, irritable conditions of the urethra. The distinction can be made usually, from the fact that in urethral disease there is no vesical tenesmus, or if any, it is much less than in cystitis. There is acute pain in the act of urination, and a burning sensation in the urethra, which some-

* I have seen one very interesting exception to this general rule. The lady had a complete prolapsus for many years, and when in the erect position she could retain her water for an ordinary length of time, but when she lay down in bed the most urgent desire to urinate came on, and she could only retain a very small quantity of urine. The cause of this I found to be inflammation of the neck of the bladder. When in the upright position the urine settled down in the dependent portion, but while recumbent the pressure came on the tender part.

times causes sympathetic vesical tenesmus; but when that passes off the bladder will tolerate distention to the fullest extent.

The causes of cystitis are numerous, much more so than in the male subject. Direct injuries frequently give rise to inflammation of the bladder, and stand first in the list of causes. In ordinary labor, especially in those who have borne many children, the bladder is pushed down between the head of the child and the symphysis pubis, and is less or more bruised, which occasionally causes cystitis. In tedious and difficult labors, and in instrumental deliveries, the dangers are greater still to the bladder. Among other causes are the careless or rude use of the catheter; the retention of the urine for an extraordinary length of time, either from carelessness or want of convenience—a misfortune to which ladies are very liable.* The decomposition of urine, is caused by imperfect evacuation of the bladder in cases of extreme prolapsus vesicae, and irritation from abnormal conditions of the urine. It may also arise by the extension of inflammation from neighboring organs, such as vaginitis, metritis, pelvic peritonitis or cellulitis, and occasionally from gonorrhoeal poison being conveyed into the bladder.

Certain diseases of the general system affect the bladder, such as the eruptive fevers. In scarlatina especially, I have noticed that the mucous membrane of the bladder suffers to some extent like the mucous and tegumentary tissues elsewhere. Sudden chilling of the feet, limbs, and lower portion of the trunk has sometimes the effect of causing vesical catarrh.

TREATMENT OF CYSTITIS.

Cystitis requires both constitutional and local treatment, and with all it is, or has been, an exceedingly troublesome disease to manage. The constitutional treatment is such as will render the urine most agreeable to the bladder, and relieve, as far as possible, the suffering of the patient. The cause, whatever that may be, should be removed if possible; and the remedies used must be adapted to the stage and condition of the inflammation. In acute cystitis caused by exposure to cold, diaphoretics should be freely used, and the patient made to rest as quietly as possible. Diuretics should be given if the urine is loaded with solid material, and the alkaline salts should be preferred. Vichy water, nitrate of potash or flax-seed tea with chlorate of potash or nitre, will answer very well at the beginning of the disease. You must be careful, however, not to push your diuretics too far. Sufficient to bring the urine to its normal proportions, and make it alkaline if naturally acid, is all that is required.

Bear in mind always that limpid urine is the most irritating to the bladder. You all know how impatient the bladder is, and how urgent the desire to urinate, when it is rapidly filled with limpid urine. One gets the best illustration of this effect when chilled by being caught in the rain in a summer day. The desire to micturate is very urgent under those circumstances, when the urine is as clear as water.

One or two leeches to the anterior vaginal wall may be tried, and hot applications to the epigastrium. To relieve pain opium is indicated. Dover's powder is very valuable, and may be given with ordinary doses of camphor. If there is any objection to anodynes given in this way, or if there is sympathetic rectal tenesmus, suppositories of morphia and belladonna should be used.

In the more advanced stages of the disease, remedies are used for their direct effect upon the mucous membrane, and much good is obtained in this way. The drugs which have the best reputation in urethritis are employed in cystitis. Balsam of Peru and of copaiba, oil of turpentine and tar water, are the chief of this class, and should be given in capsules, in the same way as for gonorrhoea.

When the pain is not severe, and the urine is loaded with mucus and pus, astringents should be given. Tannin, continued for a considerable time, is of very great value. Decoction of uva ursi, in half-ounce doses, may also be used for this purpose. In place of these I have used, with occasional good effect, a mixture composed of two ounces fluid extract of buchu, one ounce tincture of conium, and one grain and a half sulphate of morphia, giving teaspoonful doses every three or four hours.

All these remedies may be tried in cases seen early, but when they fail, or when the acute stage of the trouble is long past before advice is sought, then local treatment must be employed. The bladder should be washed out, and injections used. This you will all feel competent to do, no doubt; but I must give you some general directions as to the methods of manipulating, as I feel assured that much of the good effect of this kind of treatment is lost by the ignorant and careless use of the catheter and syringe.

I would advise you not to use the ordinary metallic catheter with one or two large openings at the end. The objection to that instrument is, that when the bladder is empty the mucous membrane passes into the opening, and is likely to be injured when the catheter is withdrawn. When the edges of the openings are sharp, as they often are, the membrane is almost certain to be wounded. I have repeatedly seen hemorrhage follow the use of such instruments. The same objection may be raised against the gum-elastic catheter, as usually made. I much prefer a metallic or hard rubber catheter, having a number of small holes in about half an inch or more of its extremity. It should also have a stopcock at the other end, which you will find convenient when emptying the bladder, and also in using injections. Besides enabling you to keep the injection in the bladder for any time desired, the stopcock enables you to regulate the escape of the last of the urine or injection. While injecting the diseased bladder, its contents are usually expelled with force, and the bladder flaps down on the end of the catheter with force enough to injure itself and cause pain. This is easily avoided by closing the stopcock, and allowing the last of the fluid to escape slowly. The hard rubber catheter is more suitable than the metallic one, where caustic injections are to be used, as it is not affected by them to any great extent.

In employing a catheter, it is usual to lubricate it with oil, but you will find castile soap and water more cleanly and convenient. The oil is apt to be rancid, and unless you have very hot water at hand the catheter cannot be easily cleaned of the oil; both which objections are avoided by using soap. In order to employ injections successfully, you must have, in addition to the catheter described, a syringe to fit into it easily and accurately. Manning's ear syringe, which

* The extent to which the bladder may be distended without rupturing is quite wonderful. My friend Dr. Bodkin recently invited me to see a lady with him in consultation, who went without urinating for four days and nights, after her confinement. The bladder reached above the umbilicus, and contained about three times the full of an ordinary pot de chambre of decomposed urine, which was drawn off by the catheter. The bladder remained paralyzed for three months afterwards, but finally regained its expulsive power. At the time I saw her, she was suffering from cystitis, brought on by the mal-treatment. In justice to the medical profession, I ought to say that this lady was at one time in her confinement, and for a long time after, by a member of this so-called "new school" of medicine.

answers very well, is simply a rubber bulb attached to a tube or nozzle. By compressing the bulb and dipping the tube into the fluid, and then allowing the bulb to expand, the fluid is drawn up into it. You then insert the tube into the catheter, and on again pressing the bulb the fluid is thrown into the bladder.

This operation, simple as it may appear to you, requires considerable skill and care in order to do it well. Much good may be gained by the proper use of this means of treatment, but great pain and distress, and even real injury, will follow if it be ignorantly employed. Observe, then, carefully these rules:—(1.) To inject only one ounce of fluid at a time; the injection may be repeated three or four times in succession, until four ounces in all are used. (2.) Inject as slowly as possible, and let the flow be regular, avoiding all sudden jerking. If you use the cylinder and piston syringe, get one that works very easily, in order that you may avoid the objection mentioned. The reason for the necessity of slow and regular injection is, that the bladder is unaccustomed to sudden distention, and any rapid expansion causes great distress, and really injures the organ.

Simply washing out the bladder is often beneficial, and it ought to be frequently repeated. It should always be done before using any medicated injection. Warm water is usually employed, but the addition of chlorate of potash or common salt makes it less irritating to the bladder. I prefer the common table salt, using about sixty grains to the pint of water. It is generally conceded that salt and water is more acceptable to serous and mucous membranes than any other fluid, because more like the normal secretion of these parts.

Having prepared the bladder for local applications or injections by carefully washing it out, the material to be used may be selected from a long list of remedies. I shall only mention a few of those which I believe to be most valuable. I need hardly tell you that anodynes have been tried most faithfully. The painful character of the disease suggests their use, but you may be surprised to learn that they are not reliable or very effectual. The mucous membrane of the bladder was not intended to absorb, and therefore we get very little of the anodyne effects of opium or any of its preparations, when injected into it, even when the dose is very large. Should there be ulceration, then the local and constitutional effects of morphia may be produced by absorption. Braxton Hicks uses one or two grains morphia to the ounce of water as an injection, allowing the patient to retain it as long as possible, and he claims good results from its use. Remedies which produce local anaesthesia, or quiet local irritation, do relieve the pain to some extent, but not altogether by any anodyne action, such as we get from opium given by the mouth or rectum.

The astringent and alterative injections most beneficial and most commonly used are nitrate of silver, sulphate of zinc, tannic acid, and acetate of lead. My rule is, to use one or two grains of either to the ounce of warm water, and to increase the quantity if no good effect comes from the small doses, but carefully avoiding injections strong enough to cause much pain. I have used, in cases where everything else failed, four grains of carbolic acid to the ounce of water, which has relieved the distress for a time, but I am not prepared to say that any permanent benefit followed. Chlorate of potash is valuable, and perchloride of iron is said to be useful. Infusion of hydrastis canadensis has been used, and great virtue is claimed for it. I have tried it, and believe that it is good in some cases, but still it fails, like the rest, in

others. When the urine is alkaline and offensive from long retention, which is occasionally the case in pro-lapsus of the bladder, then nitro-hydrochloric acid should be used, of the strength of two minims to the ounce of water. Whenever pain is caused by any of these astringent injections, morphia should be used after.

In obstinate cases a strong solution of nitrate of silver is one of the most reliable remedies. Twenty grains to the ounce of water has been used with great benefit, and it does not cause as much pain as you might suppose. Very small quantities only can be used at a time, not more than five or ten drops. The only trouble which I experienced was to be sure of getting that small quantity in, and no more. I have finally succeeded, by adopting the following plan, which I recommend to you. Take a number 1 or 2 elastic catheter, and attach it to a small graduated syringe, say a hypodermic or hard-rubber syringe, charge this with your solution of nitrate of silver. Introduce the ordinary catheter and draw off the urine, then wash out the bladder with water. Then carry the small elastic catheter through the catheter already in the bladder, and inject the five or ten drops. Remove the catheter attached to the syringe and inject a little water through the larger catheter. This will force in the last drop of the solution, and at the same time dilute it and prevent any deep or severe caustic action.

Normal urine has been highly recommended as an injection in cystitis. The urine from a healthy person is obtained and used in the same way as the other injections described. I have always looked upon this treatment with a little suspicion. It may be of value in cases where, from some derangement of the general system, the urine secreted is abnormal, and therefore irritating to the bladder, and where constitutional treatment cannot remove that condition of things. When the urine secreted can be kept in a normal state, it must, it seems to me, be as acceptable to the bladder as the same kind of urine from another person. Theoretically you would expect that healthy urine poured into the bladder from the kidneys would be more likely to cure cystitis than if it were injected through the urethra. However, this method may be of value; but one thing is certain, it fails like all other injections in certain cases.

One great obstacle often met in using injections is a tender or inflamed urethra. I will reserve what I have to say on this subject until I take up the diseases of the urethra, but meantime give the following excellent suggestion of Braxton Hicks in treating such a complication. When the introduction of the catheter is very painful, he advises carrying it up to the sphincter, and then by gentle yet firm pressure to force the injection into the bladder. This is a valuable practical point well worth remembering.

A valuable addition to these direct methods of treating the bladder is employed by my friend Dr. Robert Newman, of New York, who has made some useful contributions to the therapeutics of vesical disease. He employs the endoscope to make the diagnosis, and makes direct applications to the diseased parts through that instrument. In ulceration, he has been very successful in his practice. He applies a solution of nitrate of silver—twenty grains to one drachm water—to the ulcerated surface, and by carefully regulating the amount used, finds that the pain is less than when a weaker solution is used in the ordinary way. For a full account of this matter, I refer you to the *Transactions of the Medical Society of the State of New York for 1870*.

With all the means of treatment yet described you will be unable to cure some of your worst cases of chronic cystitis. Indeed, you will fail sometimes even to relieve their suffering. Such unfortunate subjects have usually been set aside as incurable, and even now we have cases which surpass our skill. But a great advance has been made in the treatment of those obstinate cases, by using measures to fulfil the chief indication in the therapeutics of inflammation—rest. The great trouble has been to secure sufficient rest to the bladder. Dr. Emmet has accomplished this by establishing a vesico-vaginal fistula, which maintains complete drainage. Relief is at once secured for the patient, and the inflamed and ulcerated surface, which is no longer fretted by the urine, heals up in the course of four or six months. The fistula is then closed by the usual operation. This may be considered a great triumph of science, but unfortunately it is rather too complicated a measure to become general. Making a vesico-vaginal fistula, and then closing it, are operations easily performed by Dr. Sims or Emmet, with the assistance of trained hospital nurses; but many of you would find it no easy task. Taking this view of the subject, that plan of management ought not to be tried until all other means have failed, and then only by those who have had practice in that department of surgery.

Another objection to this treatment is, that while the patient is relieved from pain she is made distressingly uncomfortable by the constant trickling of urine from the fistula. I have tried to obviate this trouble to some extent by using a hollow globe pessary, made of hard rubber, with a tube attached to it. The globe is thickly perforated with small holes all round, except for about half an inch from where the tube begins. The globe is introduced into the vagina, and the tube projects through the introitus. The urine collects in the globe, and escapes through the tube; and by attaching a piece of flexible tubing to it the urine can be conveyed into a vessel. When the introitus vulvæ is small and the sphincter vaginae perfect this answers very well, especially during the night, when the patient is in the horizontal position. When worn during the day it is necessary to have a rubber bag attached to the leg of the patient, to act as a receptacle.

I was led to devise this way of relieving patients with vesico-vaginal fistulae by having one under my care who was in no condition to be operated on for the cure of fistula, owing to general ill health. She also had severe vulvitis, and the urine constantly passing over the inflamed surface drove her almost insane. Her suffering was terrible; so to relieve her until I could operate I had made the perforated stem globe pessary, or whatever you may see fit to call it. In case you ever should have to make a fistula for the cure of cystitis, you can try this method of keeping your patient clean and comfortable.

I come now to what I believe to be the most practical and important part of the treatment of these obstinate cases. I allude to drainage by means of the self-retaining catheter. About three years ago I had a very troublesome case of cystitis, which I faithfully tried to relieve by all the means at command, but without success. My patient was obliged to urinate every fifteen or twenty minutes, day and night, and the pain and want of rest were wearing her out fast. In the hope of securing rest at night I introduced a Sims' self-retaining catheter, with a rubber tube attached, to convey the water to the urinal. The result was very gratifying. She could sleep well, and gained in health and strength rapidly, and the cystitis gradu-

ally improved. Since that time I have resorted to drainage in all the cases which resisted the ordinary treatment.

A description of this plan of treatment will be found in the Proceedings of the New York Obstetrical Society, recorded in the *American Journal of Obstetrics* for February, 1874. This method has been successfully practised by Hunter McGuire; a complete history of his case being published in the *Richmond and Louisville Medical Journal* for June, 1874. Dr. McGuire took a piece of tubing, about twelve inches long, and made holes in it about four inches from the end with a shoemaker's punch. He passed a silver tube into the bladder, and then pushed the gum tube through it until the perforated four inches were coiled in the bladder. This was retained in place by tapes fixed to the tube, and to a bandage passed round the patient's body. The tube became obstructed by mucus, but was easily cleared by injecting warm water through it. But this long piece of tubing being frequently expelled by the bladder, the doctor tried a shorter piece, and found it was more readily retained. The patient, after a time, went about and attended to her household duties, while wearing the tube, and in about four months made a perfect recovery.

This method of drainage is an improvement on Sims' catheter, but still is not all that we require. One of the best instruments for drainage is a catheter devised by Professor Goodman, and described in the *Richmond and Louisville Medical Journal* for February, 1869, as being used in the treatment of vesico-vaginal fistula; and I have recently learned that he has used it for years in treating cystitis. The following is Dr. Goodman's description of his catheter:—"It is about two inches in length, and bent to correspond to the curvature of the urethra; at the lower or external end there is a button ten-sixteenths of an inch in diameter, and at the other or internal end a shouldered, cup-shaped expansion, varying from five-sixteenths to seven-sixteenths of an inch in diameter, and bevelled on the convex aspect of the instrument, in order to make it easier of introduction, and perforated with a number of small holes. The stem, intervening between these two portions, is one and one-half inches in length and a quarter of an inch in diameter, with as large a bore as is compatible with the requisite strength. This catheter is self-retaining in all positions of the patient, first, by reason of the bulb at its upper extremity, which passes beyond the urethra into the bladder; secondly, on account of its curved shape; and thirdly, in consequence of the button being overlapped and grasped, as it were, by the vulva. At the lower end there is a slight projection or knob, over which an india-rubber tube may be slipped; this being inserted into a bottle at night or into a urinal when the patient is up, her person may thus be kept perfectly clean." I like this instrument better than anything yet made for the purpose of draining the bladder, but I believe that the sharp point of the conical end which rests in the bladder is objectionable, and I can see no good reason for having it so. At any rate, I intended to have the point made larger and more round, and try it.

In drainage by any method, you must remember that the instrument should be frequently removed and cleaned, and the bladder may occasionally be washed out at the same time.

Fortunate it is that we have this method of treatment now at our command. By this means we can restore to health and comfort the majority of those cases which have hitherto been considered hopeless.

When the cystitis is due to or is accompanied by prolapsus of the bladder, a pessary should be used to

keep the organ in place. Sometimes you will find a case where this cannot be accomplished by any mechanical support. In these circumstances elytrorrhaphy is necessary, *i.e.*, a section of the anterior vaginal wall should be removed, and the edges of the wound brought together in the way devised by Dr. Noeggerath, and described in THE MEDICAL RECORD several years ago.

Progress of Medical Science.

A CASE OF HEMORRHAGIC CUTANEOUS SYPHILIS.—Dr. Bälz reports the following case: A blood-red exanthem suddenly made its appearance in the night, without any premonitory disturbance, covering the whole body, but being most marked upon the back, buttocks, upper arm, and thighs, of a patient whose syphilitic infection dated about a year back, and who at the time was suffering from an affection of certain joints, *viz.*, of the little finger, wrist, right elbow, and both feet. This affection of the joints was subsequently shown to depend upon a hemorrhagic effusion into the articular cavities and the peri-articular tissues. The eruption was partly discrete, from the size of a millet seed to that of a thaler, partly confluent, consisting of dark-red blotches, which faded off on the following day, becoming subsequently reddish-yellow, and having scales. The cheeks and eyelids were livid and swollen, the gums perfectly normal. In some places the skin had a greenish-yellow color, as if from scorbutic hemorrhages. The urine was dark, clear, acid, and contained neither blood nor albumen. Simultaneously with an attack of pleuro-pneumonia, which came on four days later, there was a new effervescence. Applications of ice were made to the chest, and at its seat extravasations of blood took place in the skin. This eruption resembled patches of urticaria, lasting for three or four hours as blotches, then becoming papular, and sinking to the ordinary level after 24 or 35 hours, the skin meanwhile being oedematous and sensitive to the touch. The patient's general condition became normal again after two days, although the experiment of applying an ice-bag to the skin again called forth the same phenomena. At the end of four weeks he passed from under observation, retaining only some pigmentation of the skin. The affection was decided to be syphilitic, from the form, color, seat, and polymorphism of the eruption, and from the presence at the same time of other specific manifestations. Bälz therefore concludes that the syphilitic poison determined a hemorrhagic diathesis, the proximate cause being unknown. He also refers to two other and similar cases.—*Archiv für Hilkunde*, XVI.—*Rundschau*, Sept. 15, 1875.

INTERNAL STRANGULATION OF THE INTESTINE BY CICATRICES DUE TO AN HEMATOCELE.—M. Antoine Magnin, Hospital Interne, reports the following case: A woman was admitted to the hospital suffering from obstinate constipation and abdominal pain, with tenderness in the left iliac fossa. The bowels had not moved for fifteen days. The patient had been delivered of a seven-months' child one year before. Two months after the delivery her menses had returned, but with only scanty discharge, and accompanied with prolonged pains in the abdomen. At the time of admission to the hospital the menses had not appeared for

two months. During the succeeding days the pains continued and increased, and were associated with vernicular contractions of the intestines, which were distinctly visible externally. On making a vaginal examination the uterus was found to be fixed in an immovable position, and in the vaginal cul-de-sac a hard surface was felt, which extended somewhat to the left of the uterus. The symptoms grew more severe, the contractions became more painful, the intestines were tympanitic, and vomiting began. The vomited matters were at first simply alimentary, and afterwards fecal. The patient gradually sank, and died in collapse about one month after her admission to the hospital. At the autopsy signs of a recent peritonitis were found in the pelvic cavity, with a slight serous effusion, but no fecal matter. The large intestine was greatly distended, and filled with feces. On a line with the posterior superior border of the uterus a circular strangulation was found, which had been produced by cicatricial bands, which united the whole of the posterior portion of the uterus to the rectum and parts adjoining. A short distance above the strangulation a perforation was found, through which, on using some little force, a portion of the contents of the bowel could be forced into the peritoneal cavity.—*Lyon Medical*, Sept. 19, 1875.

CASE OF RHEUMATIC HYPERPYREXIA CURED BY ONE COLD BATH.—Dr. Sidney Ringer reports the case of a young woman, aged eighteen, who had been the subject of an attack of acute rheumatism. On the fifth day of her illness, the temperature was 102.8°, and remained between 102° and 104° for four days, when the fever gradually declined. She had pericarditis and endocarditis, and an attack of pleurisy with slight effusion on the left side. On the eighteenth day the fever had almost gone, and although she had not left her bed, she was considered quite convalescent. On the nineteenth day, however, the temperature rose to 103.6°; and the same night it was 104°. Early on the twentieth day, it was 104.4°; and at noon 106°. During the previous night she had been very delirious; and as the temperature rose, she became much worse. At noon (twentieth day), she was rapidly becoming comatose, could be roused, but with much difficulty, and had lost her sight. It was then determined to try the cold bath treatment. She was placed in the bath, and five minutes afterwards the temperature (in the rectum) was 106.2°.

In half an hour, thirty-five minutes after entering the bath, the temperature had fallen to 102.2°. Ten minutes later she was removed from the bath and the thermometer showed 101.2°, and thirty-five minutes afterwards, 99°. For seven hours afterwards the temperature ranged between 100° and 102° (in the axilla). Unfortunately there are no notes of the temperature of the bath, but Dr. R. thinks they commenced with a temperature of 90°, quickly reduced by the addition of ice to 60°. But a small amount of alcoholics was given while the patient was in the bath. As soon as the temperature began to fall, consciousness returned. There was no delirium, and all the serious symptoms were removed during the day. The morning after the bath, the temperature was 100.6°, and on the following day it fell to 99.6°, and never rose higher. From that time the patient rapidly improved and recovered.—*The British Medical Journal*, October 2, 1875.

TOTAL DESTRUCTION OF ONE LUNG.—Dr. J. Dowling, of Tipperary, reports the case of a girl aged eighteen, who until within a few weeks of her death had been a domestic with a farmer, who, she stated knocked her down and kicked her. To this she attributed her

illness, which was characterized by a "dragging" pain in the side of the chest, lassitude and debility. Her case was diagnosed as one of pleuritic effusion, and after some time she was sent to hospital. She was then able to walk about the ward, but with a languid air and a feeble step. For two or three weeks before death, she was confined to bed; dyspnoea increased, her face became somewhat livid, and she lay upon her back. On post-mortem examination it was found that the right lung had been entirely destroyed, and the space formerly occupied by it was filled with purulent fluid. The former connection of the lung with the heart was marked by a semicartilaginous substance not more than two ounces in weight. Some serous effusion was found in the left pleural cavity, but the lung appeared healthy. The heart was of normal size. There was no fracture of the ribs, nor were there any marks of violence on the girl when she was first seen by her physician. Further investigation was prevented. The case is interesting from the fact that life was maintained until all but the whole of one lung was converted into pus, which was confined in the thorax; and also that no hemorrhage had taken place, while death from sudden hemorrhage might have been anticipated. The latter fact, Dr. D. thinks, seems to show that the process of suppuration is sufficient to occlude even vessels of the largest calibre.—*The British Medical Journal*, Oct. 2, 1875.

AUSCULTATION OF THE ŒSOPHAGUS.—Dr. T. Clifford Allbutt, after alluding to the want of attention paid to this means of diagnosis of diseases of the œsophagus, points out what he considers the best method of examination. At first, it is best to educate the ear upon a healthy subject. The subject takes a mouthful of water and swallows it at a given signal, the operator first placing a stethoscope upon the trachea anywhere between the hyoid bone and the supraclavicular fossa. The signal being given, the patient swallows, and a very distinct resonant gurgle is heard at the position of the stethoscope. This sound, which is very loud at the hyoid bone, becomes duller as the instrument is removed to deeper parts of the neck. Below the cricoid cartilage the sound is more heavy or solid in character, and the morsel is as it were shoved downwards with a "whiz." To examine the lower part of the œsophagus, he removes the instrument to the spine, and carries it down the left side of the spines of the eight upper dorsal vertebrae. Here the sound is still more distant, though still very distinct, and is like a smooth body slipping through with a sort of "cluck." The rapidity of the passage of the morsel is ascertained by putting the instrument over the cardiac orifice while a finger is placed upon the larynx. The moment of commencement of deglutition is known precisely by the rise of the larynx; the moment of its completion is recognized by the ear. The rate of the swallow varies a little in individuals.

The swallow may be heard to the right of the vertebral column in cases where the œsophagus has been pushed to that side by tumors.

The energy of the swallow should be considered apart from its rapidity. Almost all changes in the inner surface of the tube, Dr. A. says, may be regarded as diminutions of its calibre, and as checks to its peristalsis; so that where disease exists, be it ulcer, contraction or tumor, we hear there a slackening of the rate at which a morsel is pushed downwards, and a prolongation of the morsel itself. He says, "One will be surprised how readily the exact site of an organic stricture can be ascertained, and how easily can be proved the nervous nature of a dysphagia which

causes no stethoscopic disturbances in the swallow."—*The British Medical Journal*, Oct. 2, 1875.

SUDDEN DEATH AFTER UTERINE INJECTION OF IRON.—The following case was reported by Dr. Cederschöld before the Swedish Medical Society, and it is of interest, as being another instance where injection of fluids into the uterine cavity has been followed by sudden death. The patient was pregnant for the second time. A considerable hemorrhage followed the birth of the child, the uterus did not contract fully, and the fundus could be felt over the pubes. Ergot was of little use, and the hemorrhage recurred from time to time. Eighteen days later a strong solution of the perchloride of iron (1:7) was injected into the uterus. Every precaution was taken; the syringe was freed from air, the pressure on the piston was gradual, etc., but when the injection was half completed the woman suddenly complained of pain in the breast, stretched backward, drew a few short breaths, and was dead.

A post-mortem examination was made the next day. The small intestines were actively congested; a few spoonfuls of thin blackish fluid were found in the fossa of Douglas, and on the peritoneum in that vicinity there were numerous black spots. The uterus was pretty firmly contracted, was 11 centimetres long, 9 centimetres broad at the fundus, its greatest thickness 4 to 5 centimetres; the uterine walls at the middle 14 millimetres, at the fundus 10 millimetres. The interior of the uterus and vagina was stained dark-brown. The interior of the uterus was uneven and covered with a reddish granulation tissue, with the exception of the sides and fundus, where three superficial oval ulcerated surfaces were found, each 4 to 5 centimetres long. Here the uterine substance was exposed, had a ragged surface, in the centre of which there were leaf-like, somewhat firm structures 1 centimetre high and 3 long. These were intimately united with the underlying tissues, and consisted of organic muscular fibres. At the sides of these formations there were open-mouthed vessels, some of them large enough to admit a fine sound, which then passed into the larger veins of the uterus. These were slit up and followed into the hypogastric and iliac veins, and the vena cava inferior. The blood in these veins was found markedly coagulated, and stained brown. Bubbles of air were also found in them. The same condition was found in the right side of the heart. The lungs and other organs presented nothing abnormal.—*Hygica*, August, 1875.

REDUCTION OF A STRANGULATED FEMORAL HERNIA BY LASSEN'S METHOD.—A woman of 53 had suffered for three years from a femoral hernia of the left side, and had never worn a truss. Symptoms of strangulation had existed for thirty-two hours when she was seen by Dr. O. Hase. After all the ordinary modes of reducing it had been tried in vain, Hase resorted to the method of taxis which Lassen recommends, based on his theory of the mechanism of strangulation; viz., that the incarceration is due to obstruction of the efferent end of the intestinal loop, which on its part is caused by distention of the afferent end compressing it at the neck of the sac. The lateral movements of the whole hernial tumor, which Lassen advises with the view of emptying the efferent end of the intestine, were in this case crowned with success, the bulk of the tumor gradually shrinking and the whole slipping back rather suddenly at the last, with entire relief of the symptoms.—*Centralbl. f. Chirurg.*, No. 26, 1874.—*Rundschau*, Sept. 15, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

GEORGE F. SHRADY, A.M., M.D., Editor

PUBLISHED BY

W. M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, November 27, 1875.

THE HEALTH OF THE PEOPLE.

If common sense were a conspicuous element of human nature, there would be but little necessity for the assembling of Public Health Associations to remind the public that it had a health to care for. Unfortunately the masses are woefully lacking in this most uncommon sense, and require to be educated to an appreciation of such vital agents of self-preservation as tend to ward off disease, diminish the blighting force of epidemics, and place communities in the direct path to a condition of general salubrity. We are glad that this recent meeting of the National Health Association enjoyed so much publicity as was given it in the daily press of all the larger cities of the country, for the very reason that the latter offers the most direct avenue to the sympathies of the people. Some curiosity must naturally be excited in the latter to learn why so much space is accorded to what is to them almost a novel subject, in these days of newspaper sensationalism, and the sanitary movement thus rapidly gains a foothold. The people must never tire of the theme; health boards and associations must continue to impress its importance, and the daily newspapers, with their thousands upon thousands of readers, must perpetually repeat the story. The medical press reaches a different class of readers, but many of these are mere routinists, who think more of the cure of the sick than of the care of the well among them. Some of them—a few only, we hope—see more pecuniary profit in the practice of their profession, and give but little heed to measures of prevention. When we reflect upon the noble and far-reaching objects of this Public Health Association, we wonder that its meetings are not massive gatherings of men in every department of life and occupation, instead of the comparatively small number of sanitarians who were present at this last annual gathering. As was suggested by several of those who addressed that body,

and by one especially whose text was the popularization of sanitary science, let the people know what the care of their health implies, covering as it does the prevention of sickness and deaths not only in individuals, but in communities, the proper regulation of habits of eating, drinking, and cleanliness; the supply of air, light, and water; the prevention of epidemic and epizootic diseases; the control over factories to abate nuisances; the hygiene of the mind, as involved in the regulation of study; the building and discipline of schools, asylums, jails, reformatories, and the prevention of mental disease, both emotional and intellectual, whether assuming the form of insanity or crime.

Are these subjects not interwoven with every phase of human existence? And yet unless brought home practically to the masses as a question of dollars and cents, as was done in one or two of the papers read before the Association, a permanent impression is with difficulty made upon them. Children will still be the involuntary victims of violated public hygiene in the ill-ventilated school-room, where insufficient breathing-air will be apportioned out to them by blundering builders, and when they grow up to unhealthy manhood and womanhood will, we fear, still continue to be exposed to dangerous sources of sickness and death, until the principles of sanitary science become the inheritance of every trade and profession.

Having thus stated the great objects of this Association, we have a slight criticism to make on the manner in which that body occupies the time of its members. Where so many papers are read, they must necessarily be of different degrees of merit and appropriateness. Some have merely a local importance, and are of but little general consequence; in other words, the health of some special community might be improved if the recommendations embodied in the paper were carried out, but the sanitary unsoundness of the rest of the country would still remain unaffected. It would be of little practical moment, for instance, if some of the submerged lands in certain sections of the Union were drained off to the sanitary and pecuniary profit of the neighborhoods interested; the world beyond would not be the more happy from the change. We think some sort of provision should be made in advance of the annual meeting for the presentation of such papers only as will have a widespread influence in promoting the cause of human health.

So many papers were read at the recent meeting, that discussion of points involved was almost out of the question. Let there be hereafter a due admixture of both reading and discussion, for in the friction of practical minds on practical subjects great truths may be eliminated that will inure to the general benefit. We trust that the next annual meeting of the Association, at Boston, will be so numerously attended that spontaneous discussion of sanitary matters, after the reading of papers, will be of frequent occurrence.

HOMŒOPATHY IN THE UNIVERSITY OF MICHIGAN.

IN answer to an inquiry by some of the students of the Medical Department of the Michigan University, Prof. Palmer is reported to have said in substance: "With Dr. Sager it was a question of only two hundred dollars, while with us (the Faculty) it was a question of eighteen hundred dollars." If there is any real foundation for this assertion it would appear that the matter of principle is not the only one which has actuated the said faculty in the stand which they have taken. We sincerely hope that some reasonable excuse can be offered for lowering the dignity of the position assumed to the meanness of a pecuniary consideration.

THE PRESBYTERIAN HOSPITAL AFFAIR.

WE are informed that a large minority of the Board of Managers of the Presbyterian Hospital, all laymen but one, have resigned their positions. This action is understood to be due to their failure to influence the majority to rescind their unjust action in dropping some of the medical staff, against whom there are no charges—a subject that has been fully discussed in THE RECORD. We have no doubt but that the members of the medical profession will take immediate steps to show their appreciation of the course of these gentlemen in thus bravely standing up in vindication of their honor. Nearly all the members of the medical staff have also resigned, all efforts at an adjustment of the difficulties having failed.

PROFESSOR LORAIN, of Paris, whose sudden death occurred so recently, has left in the memories of his confrères many incidents which illustrate the unselfishness of his character. Even the circumstances of his death serve to show how self-sacrificing he was. He was busy in his study preparing his first lecture on the History of Medicine, which he was to deliver in a few days, when a patient called to ask him to attend a child. The servant had received orders to say, "Not at home," but the poor father insisting, was let in, and Dr. Lorain, notwithstanding his wife's reminder that he was not well, went out, took an open carriage, and climbed the six flights of stairs which led to the room of the sick child. He had scarcely reached there when he begged to be laid on a bed. Two physicians were summoned, and found him cyanosed and convulsed, and in about twenty minutes he was dead. As a proof of the extraordinary effects which may follow arbitrary regulations, it is said that Dr. Grancher, one of the physicians in attendance, went to the office of St. Antoine Hospital, to borrow a stretcher with which to take the body of the professor home. The official in charge sternly refused to permit a stretcher to be taken out of the hospital, and though Prof. Lorain had been for many years physician to this hospital, and was at the time physician to La Pitié, his friends were obliged to obtain the necessary stretcher elsewhere.

As another evidence of his unselfish nature, it is related that in 1868, Lorain was inscribed on the list of savants who were to receive the Cross of the Legion of Honor. Hearing of this, he at once used all his influence to get the name of an elder colleague substituted for his own. This was done, and Lorain, had to wait some years before receiving the wished-for Cross for himself, as he obtained it only in August, 1875.

Reports of Societies.

AMERICAN PUBLIC HEALTH ASSOCIATION.

THIS body met at Baltimore, Tuesday, November 9th, and continued in session for four days. The list of those present included many prominent sanitarians. The following officers, elected in 1874, were present: *President*, Dr. Joseph M. Toner, of Washington City; *Vice-President*, Dr. Henry Hartsborne, of Philadelphia; *Treasurer*, Dr. John H. Rauch, of Chicago; *Secretary*, Dr. Elisha Harris, of New York. Drs. Stephen Smith, N. Y.; J. A. Stewart, Md.; J. J. Woodward, U. S. Army; J. S. Billings, U. S. Army; Moreau Morris, N. Y., and A. N. Bell, N. Y., were the Executive Committee.

The

ADDRESS OF WELCOME

was appropriately given by Dr. Stewart, Health Commissioner of Baltimore, and Chairman of Committee of Arrangements. Dr. Toner then delivered an Introductory Address as President of the Association, in which he alluded to the necessity of educating the masses of the people to a proper understanding of hygienic laws and principles. He also referred to the great progress evinced everywhere throughout the country in the furtherance of sanitary measures, and to the numerous American contributions recently made to the literature of the subject.

Dr. EZRA M. HUNT, of New Jersey, in a paper on

"DWELLING-HOUSES IN THEIR RELATIONS TO HEALTH,"

entered into the full details of the construction of houses, from the basement upward, showing, for example, that unless cellars were properly drained they were unhealthy for the purposes proposed; that walls should be porous to exclude draught, but admit atomized air; that fireplaces should be made available for ventilation, etc.

"The Sanitary Condition of American Watering-Places" was discussed by Dr. Henry Hartsborne, of Phila. He thought the same sanitary regulations should be in force in a watering-place as in a camp. These precautions were often neglected, and consequently places of summer resort sometimes suffered from the visitations of disease. Wells of drinking-water and cesspools were often in too close proximity. He suggested the proper method of protection against contamination of the soil, and that the sanitary records of watering-places should be transmitted to the Secretary of this Association.

Dr. ELISHA HARRIS, of New Jersey, then alluded to the

PROGRESS OF SANITARY WORK IN THE UNITED STATES DURING THE YEAR PAST;

to the establishment of State Boards of Health in several States; to the results already accomplished in Georgia in the few months that have elapsed since the State Board was established there; and to the effective researches made by the Massachusetts Board, who annually publish valuable reports of their labors. After the reading of this paper, Dr. Ezra M. Hunt, of New Jersey, stated that he had great faith in the good results to be attained by educating the public mind; that boards of health should not be too medical in

their composition. Dr. Hartshorne thought that these boards constituted the most efficient method of rousing the public.

LEGISLATION UPON SANITARY MATTERS

was discussed by DR. E. LLOYD HOWARD, of Baltimore, especially in its relation to that city, which had long suffered from unjudicious and costly, but ineffective legislative interference in such matters.

DR. F. B. HUGH, of Lewis Co., New York, read a paper bearing upon

THE EFFECTS OF FORESTS AND THE CULTIVATION OF TREES ON THE PUBLIC HEALTH,

alluding also to their influences as agents for the production of disease, according to the varying conditions of temperature, moisture, electricity, etc. Minute observations had been made by Prof. Ebermayer, of Bavaria, and were quoted in this paper, exhibiting changes of temperature in the woods at different altitudes and seasons.

Mayor Latrobe, of Baltimore, presiding at the evening meeting, alluded to the care taken of the human health in the palmy days of Rome, when the Archiatri Populares, or State Physicians, constituted a college, whose duty it was to devise means for the preservation of the public health.

PROF. HENRY COPPEE, President of Lehigh University, considered

HEALTH SUBJECTIVELY,

as to the habits of individuals, and man's study of his own wants and requirements for health-preservation, so that hygiene may be properly appreciated by each one for himself.

Dorman B. Eaton, LL.D., in a discourse on

SANITARY ADMINISTRATION,

considered that the majority of people understood the necessity of sanitary laws and precautions, and how to apply them, but thought that in these days, when the whole world may be agitated by the prevalence of a very distant localized epidemic, that this country ought not to be left so very far behind by monarchical governments, in all measures for the improvement and preservation of human health.

On Wednesday morning a number of new members were elected, and the Treasurer's report read, after which Dr. JOHN S. BILLINGS presented a paper on a

PLAN FOR SYSTEMATIC SANITARY SURVEY OF THE UNITED STATES.

The most important facts yet collected have been those furnished by medical army officers at the various military posts. Schedules were exhibited, for uniform registration, to be filled for all cities of 5,000 inhabitants and over, on such points as location, population, drainage, market supply, health laws, etc., etc. A committee was, on motion of Dr. Busey, appointed to carry the plan into effect, and consists of the following gentlemen:

Dr. Elisha Harris, New York, chairman; Dr. E. M. Hunt, New Jersey; Dr. H. B. Baker, Michigan; Dr. John H. Rauch, Illinois; Dr. James A. Stewart, Maryland; Dr. C. B. White, Louisiana; Dr. J. N. Logan, California; Dr. J. S. Billings, U. S. A., Washington; Dr. P. H. Brown, Dr. Joseph M. Toner, Washington, D. C.; Dr. J. M. Woodworth, Washington, D. C., with power to add.

DR. W. C. VAN BIBBER, of Baltimore, read a paper on the

SELECTION OF SUMMER RESORTS,

as adapted especially for the treatment of the various sufferers from rheumatism, dyspepsia, debility, phthisis, etc. There are two thousand such places, visited annually by five hundred thousand persons, and it is important to select for invalids such as are appropriate for the particular affection, as many of these resorts might be injurious in some forms of disease while indicated in others.

SOIL, DRAINAGE, ETC.

Papers were then read by Prof. George H. Cook, of New Jersey, on "The Drowned Lands" of portions of that State and of New York, and by Dr. Sanford B. Hunt, of the same State, on "Soil Drainage and Atmospheric Humidity," as bearing on the causation of disease.

PROF. H. R. NASH, in a paper on

"SEWER GAS AS A CAUSE OF DIPHTHERIA, MEMBRANOUS CROUP, ETC.,"

gave an instance in which, in one family of eleven, exposed to such deleterious influences, five were attacked with diphtheria and three with scarlet fever. What prolonged cases of ill-health may result from such exposure, it is impossible to estimate.

GENERAL E. L. VIELÉ read a very elaborate paper on

"DRAINAGE, SEWERAGE, AND WATER SUPPLIES OF CITIES,"

explaining the difference between drainage and sewerage, and alluding to the fact that a knowledge of mathematics, hydraulics, chemistry, and meteorology was essential to a full appreciation of the problem of sewerage. In conclusion, he advocated the employment of the pneumatic system in this country.

The subject of the employment of

"POISONS IN AGRICULTURE AND HORTICULTURE,"

discussed by Prof. R. C. Kedzie, of Michigan, included especially an inquiry into the effects of arsenical preparations—particularly Paris green—when so used. The latter substance was stated as not likely to affect the plant when applied in the usual minute quantities, because the plant does not absorb it; but when applied to wheat or to the land on which it is growing, it appears in the grain, rendering it unfit for use.

NERVOUS DISEASES OF SCHOOL CHILDREN.

DR. ALLAN McLANE HAMILTON, of New York, presented a paper on "The Nervous Diseases of School Children," showing how imperfect school hygiene affected their nervous system. Interesting facts were mentioned, exhibiting how much mischief was caused by too close confinement in poorly ventilated school-houses, over-study, fatigue, etc. Dr. D. F. Lincoln, of Boston, and Dr. A. N. Bell, of New York, followed in the same strain, the former reading one on "School Hygiene;" the latter on "School-room Stunting," the evils of improper and unnatural treatment of the child here being particularly dwelt upon.

PROF. W. C. KERR, of North Carolina, State Geologist, read a paper on the

"DRAINAGE AND WATER SUPPLY OF SOME OF THE SOUTHERN STATES,"

after which the Association adjourned until evening.

when Prof. Stephen Smith alluded to the "Limitation of Perilous Massing of Populations in our Cities," especially as it concerned the health of the poorer classes, and the necessity of educating them in the principles of sanitary science.

PROF. F. DONALDSON, M.D., of Baltimore, followed in a paper on a congenerous subject.

"THE INFLUENCE OF CITY LIFE AND OCCUPATIONS IN THE DEVELOPMENT OF CONSUMPTION,"

treating of the effects of impure air, the introduction of foreign matters, as finely divided flax, flint, steel, etc., into the lungs, the absence of sunlight, etc., as exciting causes of this disease. Sedentary life, insufficiency of food, etc., were also discussed, and similar relations of cause and effect.

OFFICERS ELECT.

On Thursday morning, officers were elected for 1875-76. These were as follows: President, Dr. E. M. Snow, R. I.; Vice-presidents, Drs. John H. Rauch, Ill., and Prof. F. A. Walker, LL.D., Conn.; Treasurer, Dr. J. Foster Jenkins, N. Y. Executive Committee, Hon. A. W. Boardman, Mass.; Drs. J. S. Billings, U. S. Army; J. M. Woodworth, D. C.; Lewis H. Steiner, M.D.; Ezra M. Hunt, N. J., and Jackson S. Schultz, N. Y. Dr. Elisha Harris, of New York, was elected Secretary in 1873 for three years.

A paper was then read by FRANK HAMBLETON, Civil Engineer, of Baltimore, on

HOUSE CONNECTIONS WITH SEWERS.

showing the advantages of a general system of sewerage over the antiquated cesspools.

HOG CULTURE IN NEW YORK.

JACKSON S. SCHULTZ, of N. Y., in a paper on the "Utilization of Animal and Vegetable Refuse Substances in Large Cities," suggested that instead of throwing the garbage and offal of New York into the sea, or letting it go to absolute waste, some local point should be chosen, an island in Long Island Sound, for example, where all refuse matter, garbage, etc., from the city should be deposited, where hogs in sufficient number would devour it.

WHAT A GREAT EPIDEMIC COST A GREAT CITY (the small-pox epidemic at Philadelphia in 1871-2) was explained in an unusual way by DR. BENJAMIN LEE, of Philadelphia. What with increased expenditures by the Board of Health; loss by sickness and death and debility; diminution of travel and traffic; loss to hotel-keepers, retail dealers, etc., the cost is estimated at about twenty-five and a half millions of dollars. The figures are separately given for each item discussed.

The Association responded to the invitation of the Centennial Medical Commission of Philadelphia, to send delegates to the International Medical Congress in 1876, by appointing the following gentlemen: Drs. Toner, D. C.; C. F. Folsom, Mass.; Billings, U. S. A.; Stephen Smith, N. Y.; C. B. White, La.; F. G. Thomas, Ga.; Kodzie, Mich.; Stewart, Md.; Logan, Cal.; H. A. Johnson, Ill.

DR. THOMAS G. DEMOTT, of Harrisburg, Pa., alluded, in a paper on

"SMALL HOSPITALS OR VILLAGE INFIRMARIES FOR MANUFACTURING AND MINING POPULATIONS,"

to an act passed in 1874 by the Legislature of Pennsylvania, to provide for the support of sick and injured poor, undergoing hospital treatment in cities, out of the county treasury.

PROF. CARL PFEIFFER, of New York, in a paper on the subject of

VENTILATION,

advocated mechanical or propulgent ventilation as the most perfect system. He thought the poor should be taught that food is scarcely more important to them than ventilation.

A paper by DR. H. O. HITCHCOCK, of Michigan, investigated the relation of alcoholic drinks to health, giving the statistics of consumption of alcoholic liquors of all kinds in the United States, the sales of retail liquor dealers averaging \$48.00 to every man, woman, and child in the land. Of the insane in the country at the time of taking the last census, more than 22,000 were probably due to alcohol, and 18,000 idiots may owe their idiocy to the same cause. The loss to the nation, by the death of adults from alcohol, is estimated in value at from one hundred to nearly two hundred million dollars.

A paper on "Alcohol in Relation to Life Insurance," was read by Dr. W. T. Harrison, Jr., of Baltimore; two on Yellow Fever, by Drs. Sternberg and Harvey C. Brown, of the army; and one on North Carolina as a sanitary resort, by Dr. W. Gleistener, of that State. The "Diseases of the Indian Tribes of the United States" were described in a paper by Dr. Josiah Curtis, of the Indian Bureau, as prevailing chiefly in April, May, and June, and as including principally scrofula, rheumatism, and bowel and skin affections. Captain Jack's belligerent attitude was said to have had its origin in the jealousy of rival "Medicine Men."

In the evening, DR. STEINER, of Maryland, discussed the sanitary points that might be evolved from the question,

"AM I MY BROTHER'S KEEPER?"

and DR. ANDREW D. WHITE, LL.D., of Cornell University, addressed the Association on

SANITARY CARE AND PHYSICAL CULTURE IN UNIVERSITIES, COLLEGES, ETC.,

advocating physical exercise, the teaching of sanitary science, etc., and citing the fact that of 294 members of crews of Oxford and Cambridge, only 7 (a number not more than one-sixth of the average London death-rate in the same number), had died of cardiac and pulmonary disease.

On Friday, after the reading of a paper by DR. H. W. DEAN, of Rochester, N. Y., on

SANITARY PRINCIPLES IN HOUSE ARCHITECTURE, one on

THE POPULARIZATION OF SANITARY SCIENCE,

was offered by PROF. E. W. CLAYPOLE, of Antioch College, who advocated the necessity of diffusing information on every point involving the health of individuals or communities. He thought that inmates and criminals fared better than children do in the schools, so far as ventilation and attention to sanitary laws are concerned.

MISCELLANEOUS PAPERS.

A number of papers were read by title only, after which interesting papers were read by Dr. Elisha Harris, on General Vaccination; by Prof. James Law, M.D., of Cornell University, on "Hereditary Entailments in Domestic Animals and the Human Family;" and by Dr. T. M. Stevens, of Indiana, on "Water Filtration."

Resolutions were passed asking the co-operation of the General and State Governments for the establishment of a uniform system of registration of births, deaths, and marriages; for a Committee of Publication to examine and publish such papers in full as they may deem advisable; of respect to the memory of two deceased members, Drs. Krackowizer and Peate; and of thanks to the press.

The Association then adjourned, to meet in Boston, November, 1876.

Correspondence.

THE PRESBYTERIAN HOSPITAL AFFAIR.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Since I am no longer connected with the Presbyterian Hospital, I desire to say, through your columns, a few words concerning that unfortunate institution, for the sake of correcting in the minds of some of your readers certain impressions which I know to be erroneous.

It has been stated that when the hospital was opened, the medical profession in this city was very much dissatisfied with the selection that was made of a Medical Staff, because the "one medical gentleman" in the Board of Managers had appointed his own students to nearly every position. It is a fact that seven out of the sixteen men selected had been students in this gentleman's office; and considering the large number and class of students he had had, it was not so very surprising. The fact is, that the gentleman in question urged the appointment of only two men on the staff, of whom one had been his student and the other had not.

At the regular meeting of the Medical Board in May, 1874, the ballot for President resulted in the election of a gentleman who had never before held the office. It has been stated that the Board of Managers were "fairly incensed" at such independent conduct on the part of its Medical Staff. It would seem that such a statement must be greatly exaggerated, and I have heard it denied by more than one member of the Board. Article 3, Section II., of the Rules and Regulations of the Hospital, provides, that "the Medical Board . . . at the first regular meeting, in May of each year, shall elect a President, Vice-President," etc. Each of your readers can decide for himself whether voting for the man of his choice is an offence for which he ought to be punished by being "dropped" from the staff of a hospital.

At the annual meeting of the Board of Managers in April, 1875, Drs. Ball, Wheelock, Day, and Wynkoop were "dropped" from the visiting staff, and Drs. Hubbard, Burrall, Smith, and Woolley were elected in their stead, the change being effected under Section I. of the Rules and Regulations, which reads: "All Physicians and Surgeons connected with the Hospital shall be elected annually." We are told that this rule was copied from the Code of the New York Hospital, where it had worked well for more than a century, by "the only medical gentleman" on the Board of Managers. Suppose it was. A celebrated English jurist has said that there was not an Act of Parliament through which he could not drive a four-in-hand. Certainly no medical gentleman intended the rule to be applied in such a case as this. It was meant for cases

in which *every one* interested in the good of the hospital—the Medical Board included—were satisfied that a change was absolutely needed; for instance, if some one of the staff had become insane and refused to resign, or had become notorious as an abortionist, in which case positive proof before a court of law is well known to be next to impossible. The rule is sufficiently good as it stands; fault may well be found with the way in which it was applied.

As soon as this action of the Managers became known, Drs. Clark, Peters, Allin, Stimson, Woodruff, and myself, in one communication, and Drs. Buck and Post subsequently in another, protested to the Board of Managers against their action. Dr. Crane was absent in Europe. The remaining three members of the Board, by their silence, acquiesced in what had been done. At about the same time—early in May—the protest from the profession at large, which has already appeared in your columns, was sent in. The Visiting Committee replied to the protest of Drs. Buck and Post; the other two were passed by in silence.

The four gentlemen who were "dropped" asked from the Managers the reason. The reply came that there were no charges to be made against them, either as to their character as gentlemen, their professional ability, or the faithful discharge of their duties; but the Board of Managers insisted on their right to "drop" medical officers whenever they saw fit.

This action of the Managers was not unanimous; was taken without the gentlemen "dropped" having had any warning or opportunity to resign; and in the face of a most earnest protest on the part of "the only medical gentleman" on the Board and several of his friends. Of course it was not done out of mere caprice. The Visiting Committee engineered the affair; and when they were asked why the change was desired, the answer was, that the Resident Directress had hinted that if a change was not made she should consider that her services were no longer desired. They are men of veracity, and their statement may be accepted as a *fact*; deny it who can. The Managers appear to have concluded that they could more easily find four doctors to take these places than one new Resident Directress. The facility with which they filled the vacancies on the Medical Staff, was, I confess, surprising. The four new appointees accepted with little delay, and took their seats in the Medical Board at its next regular meeting. I am told that they say that they accepted without knowing what the condition of affairs was. As far as two of them are concerned, I cannot believe that they ever said so, for I *know* that they were informed. However that may be, will any one claim that they now retain their positions with the same lamentable lack of information?

At the June meeting of the Board of Managers, Drs. Peters, Allin, Stimson, Woodruff, and myself resigned our positions, on the ground that an act of great injustice had been done to four of our former colleagues, in that they were "dropped" without cause; that four new men had been appointed without nominations having been asked from the Medical Board; and that a perfectly respectful protest had been ignored. Remaining, under the circumstances, we would have tacitly implied our own willingness to be "dropped" in April next, if the Resident Directress should then consider it advisable.

With reference to the second reason for resigning, a word of explanation is necessary. Art. 7, Section II., of the Rules and Regulations, reads: "In case of vacancy in the Medical Board, they (the Medical Board) shall, at the request of the Board of Managers, recom-

mend suitable persons for appointment." I am informed that the gentlemen who framed this rule intended that the Managers should *always* request nominations, and that the Medical Board should *always* make them. Such would be a very rational exposition of the meaning of the Rule; this course was always taken previous to this particular instance; and since our resignations have been accepted, the Medical Board has again been asked to nominate our successors. The Managers, by their acts, acknowledge the propriety of this course when it suits their convenience; but, in the particular instance under consideration, take refuge behind the loose wording of the rule, and the fact that these were not vacancies occurring in the middle of a year, but were new appointments for the ensuing twelve months.

Our resignations were not accepted in June, but a committee of five of their own number was appointed by the Board of Managers to "confer" with us. We met these gentlemen three or four times, and on the 16th inst. they made their report, looking toward an adjustment of the difficulty. The report met with such a reception that all the gentlemen whose names were appended to it, and who were present, resigned their seats *instanter*, and the resignations of others will be presented to the Board at their next meeting.

The position of the Board of Managers is, that, when they see fit, they will "drop" a gentleman from the Medical Staff without giving him a moment's warning, a chance to resign, or the least opportunity to defend himself. It remains to be seen whom they can get to serve them on these conditions—the only ones on which a medical man can take or retain a position on the staff of the Presbyterian Hospital. It is worse than folly for members of our profession to talk about "upholding the dignity of our calling" at one moment, and submit to such treatment at the next. Moreover, this is not a question which affects only those who have lost, resigned, or still retain positions at the Presbyterian. It affects every medical man who now holds, or ever hopes to hold, a position in any hospital, dispensary, or other charitable institution in this city—probably in this country. If this action is allowed to become an established precedent, it is impossible to foresee where the evil will end. Indeed, it is already rumored that one man who occupies a seat among the Governors of the New York Hospital as well as the Managers of the Presbyterian, has said that "no one of the doctors who resigned at the Presbyterian at this crisis need expect to keep or get a position at the New York." So far from being an affair in which the medical profession, or even the public at large, "need not be supposed to interest themselves," it is without doubt, for all persons in any way interested in public charities, the most weighty and important question that is likely to present itself during our lifetime.

I have not written this communication with any harsh or spiteful feelings. Those members of the Board of Managers whom I have met have always treated me with the utmost courtesy, and I have still the good of the hospital as much at heart as any one of them. But I am thoroughly convinced that their way of treating a hospital staff is derogatory to the profession I have chosen, and can never result in the success of a charitable enterprise, or the welfare of the patients.

SAMUEL B. WARD, M.D.,

Late Visiting Surgeon Presbyterian Hospital.

MR. RAWDON MACNAMARA has been elected surgeon to Westminster Hospital by a large majority of votes.

Medical Items and News.

THE PRESBYTERIAN HOSPITAL AFFAIR—A CALL FOR A MEDICAL MASS MEETING.—The members of the medical profession of the city of New York who believe that the recent action of the Board of Managers of the Presbyterian Hospital in the matter of failing to reappoint certain members of the medical staff, against whom no charges were preferred, is injurious to the hospitals in their beneficent work, are invited to meet at the theatre of the Union League Club, Tuesday evening, Nov. 30th, at 8 o'clock, to give public expression to their views. Signed.

T. M. Markoe, A. DuBois, Lewis A. Sayre, J. W. McLane, Erskine Mason, A. Flint, Jr., H. B. Sands, F. J. Bumstead, A. Jacobi, T. Gaillard Thomas, F. N. Otis, Everett Herrich, Francis Delafield, Charles E. Hackley, William H. Thomson, D. B. St. John Roosa, James R. Wood, Horatio Bridge, J. W. S. Gouley, Charles K. Briddon, William T. Lusk, C. R. Agnew, Thomas T. Sabine, Robert Watts, Meredith Clymer, R. F. Weir, Charles McBimney, Edward G. Loring, J. E. Janvrin, Frederick R. Sturgis, Henry F. Walker, J. R. Leaming, J. P. P. White, William Polk, David Magie, J. Marion Sims, Frank H. Hamilton, Charles Insee Pardee, J. W. S. Arnold, Woolsey Johnson, R. A. Witthaus, J. J. Hull, S. F. Morris, William A. Hammond, Edward Curtis, and others whose names came too late for publication.

PROF. FRANK H. HAMILTON'S WORK ON FRACTURES AND DISLOCATIONS, the fifth edition of which has just made its appearance, is to be translated into German by Dr. A. Rose, of this city, and to be published by the celebrated firm of Vandenhoeck and Ruprecht, of Göttingen—a compliment which has not been paid to any other American book on Surgery.

DR. J. C. HUTCHINSON, of Brooklyn, N. Y., is to lecture on Deformities at the College of Physicians and Surgeons in this city during the present session.

DR. GUSSENBAUER, the clinical assistant of Prof. Billroth, has been appointed Professor of Clinical Surgery in the University of Liège, in Belgium.

THE BRITISH MEDICAL ASSOCIATION will meet in 1876, at Brighton, and the Address on Medicine will be delivered by Dr. Sieveking, the Address on Surgery by Mr. Wheelhouse, of Leeds, and the Address on State Medicine (Public Health) by Dr. Carpenter, of Croydon.

JOHN LOCKE.—A new work on the life of this illustrious man is soon to be published by Mr. H. R. Fox Bourne, to which will be prefixed a curious collection of medical memoirs and notes, showing how extensive were his studies and practice as a physician, and connecting him as a joint-worker with Thomas Sydenham, "the father of English medicine."

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

[THE MEDICAL RECORD is published every Saturday. Notices of meetings, lectures, operations, etc., intended for publication in this bulletin should be received at the office, 27 Great Jones Street, one week previous, to insure their appearance.]

Original Lecture.

UROCYSTIC AND URETHRAL DISEASES
OF WOMEN.

By ALEX. J. C. SKENE, M.D.,

PROFESSOR OF GYNÆCOLOGY IN THE LONG ISLAND COLLEGE HOSPITAL,
BROOKLYN, N. Y.

LECTURE II.

GENTLEMEN:—Progress in the study of pathology enables us to understand more fully the various changes of structure which give rise to deranged action on the part of the various organs of the body, and therefore we have more *organic* diseases on our present list, and fewer *functional* disorders.

The rule has been to call any trouble a functional disease when we could discover no change of structure in the case. On the other hand, improved means of investigation now enable us to ascertain more positively that in certain deranged functions, the organs involved are normal in structure. This is particularly applicable to the derangements of the bladder in the female.

There are several functional disorders of the bladder due to diseases outside of the organ itself, and in order that you may easily follow me in what I have to say about these derangements, let me enumerate the various ways in which the function of the bladder may be disturbed.

1. Frequent urination.
2. Difficult urination and retention.
3. Painful urination.
4. Pain after urination.
5. Incontinence of urine.

The majority of these deranged actions on the part of the bladder may be due either to functional or organic disease. Those purely functional I shall now tell you about.

In the variety of conditions of the nervous system grouped under the head of "hysteria," we often observe that frequent urination is a prominent symptom. The cause, in many cases, is the peculiar character of the urine secreted in this disturbed condition of the nervous system. The limpid urine of hysterical patients is deficient in solids, the watery portion being greatly in excess. This unnatural composition renders the urine irritating to the bladder, so that it cannot be long retained. The quantity of urine secreted is also excessive, which, together with the irritating quality of the fluid, renders urination necessarily very frequent.

But apart from the frequent urination which occurs, for the preceding reasons, in severe attacks of hysteria, we often see cases of frequent evacuation which can only be accounted for by the state of the nerves which govern the action of the bladder. When the quantity and composition of the urine are normal, and the patient can retain it without pain or distress during the night, but has to pass it every hour or two during the day, we may safely conclude that the trouble is purely functional, and due to a disordered state of the nervous system. The only condition which resembles this history is occasionally seen in prolapsus, the patient being free from trouble while reclining, but has to urinate frequently when in the erect position.

Another class of cases resembling the hysterical patients in the frequency of urinating, but differing in every other respect, we find in those who suffer in consequence of the habit of masturbation. The constant congestion and irritability of the pelvic organs, caused and kept up by the unnatural and excessive exercise of this sexual function, give rise to frequent urination. Such patients complain of general weakness, which is not accounted for by any organic disease of the general system. Nor is there disease of the bladder; it is simply enfeebled and irritable like the rest of the pelvic organs. To make a correct and positive diagnosis in such cases is by no means easy, because it necessitates our detecting the habit of masturbation, and this is usually one of the most difficult tasks for the diagnostician. It is not always prudent to question the patient regarding the habit; and even when we do, they frequently fail to comprehend the question, or they answer falsely in the negative. We are thus generally left to guess at the truth of the matter.

The symptoms developed by masturbation are depression of the nervous system, manifested by lassitude, sadness, or emotional manifestation of joy and sorrow—easily affected to smiles or tears. The eyes are dreamy and heavy, and the pupils dilated. Such subjects are excitable, irritable, and easily exhausted. They often have headaches. Nutrition is apparently good in some cases, as shown by the fair supply of flesh; still they often suffer from acute indigestion, although at times the appetite is remarkably good. The bowels are usually constipated, and the muscles are soft and flabby. The exhalations from the skin are changed in some cases, so that a peculiar odor is noticeable about such persons. This odor cannot be described, but when once experienced can be easily remembered.

In all this class of functional derangement of the bladder from neurotic causes, the symptoms vary in severity to a great extent in the same individual. The trouble is by no means regular and constant in its manifestations as in organic diseases. Whatever disturbs the nervous system will increase the disorder. The rule is, that frequent urination is the prominent trouble, but occasionally painful micturition is complained of. It is then simply a slight scalding pain experienced when the urine is passing over the irritable or chafed mucous membrane about the meatus urinarius.

Hysterical patients frequently suffer from retention of urine. Some of them complain for a time of difficulty in emptying the bladder, and finally fail to do so altogether. At other times they all at once find that they cannot urinate. There are conflicting views regarding the cause of this retention, some believing that such patients can't urinate, and others that they won't. Those who believe that the trouble is feigned, not real, do so on the ground that in this morbid state of the nervous system they enjoy catheterization, which would be distressing to any one of healthy mind and body. Others claim that in the extreme sexual excitement which occurs in some cases of hysteria, the chronic erection of the clitoris makes pressure upon the urethra, and prevents the flow of the urine through the then compressed urethra. I am satisfied that both kinds of cases occur. There are those who complain of retention when they know that the doctor will use the catheter, but they can urinate easily when they please. Others I have seen who were suffering from excessive and painful distention of the bladder, and would have gladly relieved themselves if they could. Retention of the urine from this cause occurs in the amorous, who

either do not practise masturbation, or who have broken off the habit.

The function of the bladder is frequently deranged from diseases of the general system, and by affections of the other organs of the pelvis. In many of the acute diseases, where the urine is loaded with solid constituents, urination is often painful. This symptom is usually accounted for by the fact that it occurs during the constitutional disease, and passes off, as a rule, in a short time.

The effect of malarial poison on the bladder and urethra is very peculiar, and requires a notice in this connection. The trouble produced in this way has been called urethral fever, and is described as an inflammation of the mucous membrane of the urethra. It might more properly be called malarial fever of the urethra. As I have observed this affection, the bladder and urethra are usually both affected, but I do not consider the disease one of a well-defined inflammatory character. There are usually symptoms of malaria present, but not necessarily chill and fever. On the contrary, I believe that I have observed the trouble more frequently in remittent than in intermittent fever, and very often where the constitutional symptoms were not more than a slight derangement of the digestive organs with moderate elevation of temperature in the after part of the day.

The symptoms vary, but usually are as follows:—The patient complains of frequent desire to urinate, and some vesical tenesmus; severe burning pain on passing water, with stinging and burning in the urethra after urination. The history of such cases resembles acute gonorrhœal urethritis so far as the abruptness of the attack and the tenderness and pain of the urethra are concerned, but there is usually no discharge, or at least very little. Under the proper treatment the disease disappears as promptly as it comes on. In many cases the suffering is greatest in the afternoon and early part of the night. The treatment is simple, and usually very satisfactory. Quinine* in full doses for one day, followed with small doses before meals for a week, will cut short the trouble, and prevent its return. The digestive organs require attention when they are out of order, as they generally are.

Functional disorders of the bladder, caused by diseases of the other pelvic organs, are frequently met in practice. In this class the bladder trouble is secondary to some primary and more important affection, but the derangement of its function is often the most troublesome and most prominent symptom, hence it is important to understand its relations to the primary disease in order to make a correct diagnosis. This class of functional disorders frequently resemble in history some of the organic diseases of the bladder, so that care is necessary in order to distinguish the one from the other. What I may say on this subject will have reference to diagnosis only. When we know that the trouble of the bladder is due to disease of some other organ, attention is at once turned to the primary trouble; but we must keep in mind these facts when we are investigating the derangements of the bladder.

Diseases of the rectum often affect the bladder sympathetically. Irritation and pain of the rectum, from any cause, affect the bladder less or more. Chronic hemorrhoids will cause frequent urination, and so will rectal fissures, especially after defecation. Abscesses in the neighborhood of the rectum will frequently cause retention of the urine. Very troublesome irrita-

tion of the bladder comes from ascarides. The itching of the anus and rectum caused by these troublesome little worms keeps up an almost constant desire to urinate. Children are the most troubled with these parasites, but women often suffer in the same way.

Acute pelvic peritonitis and cellulitis cause great distress in many cases by their effects on the bladder. A constant desire to urinate, without the ability to make straining efforts to accomplish the object, are very often observed in all these acute pelvic inflammations. The disturbance of the bladder is of course only a symptom of the more important and primary trouble, and requires only to be mentioned here. The after-effects of pelvic peritonitis on the bladder is what I especially desire to call attention to at present.

The adhesions formed by the products of the inflammation of the pelvic peritoneum are in some cases sufficient to prevent the distention of the bladder and frequent urination is then a necessity. This derangement of function generally exists alone. The urine is retained without trouble up to a certain amount; it is passed without pain, and no vesical tenesmus follows evacuation. Unless the contraction of the bladder is extensive and the frequent necessity to urinate very troublesome, patients rarely consult us for the trouble.

Resembling this form of deranged function of the bladder are the troubles which come from displacement of the uterus. In all dislocations of the uterus the bladder suffers less or more. In prolapsus the bladder is drawn down, and cannot expand with the same facility, or else the extra traction on the utero-vesical ligaments produced by the prolapsus increases the irritability of the bladder. Whatever the explanation may be, the fact is that in prolapsus uteri the subject cannot retain the urine for the usual length of time.

Frequent urination from this cause is as marked in prolapsus in the first degree as in more advanced stages of the trouble. When the displacement has existed for a considerable time, the bladder accommodates itself to the new relation of things, and the calls to urinate become less frequent.

In complete prolapsus of the uterus and bladder, we find, in place of frequent urination difficult urination, and in rare cases retention. I presume that in such cases the bladder is never completely emptied. The little urine which remains decomposes, and in time causes cystitis, which greatly increases the suffering of the patient. Such cases are very much like the cystitis which in old men comes from partial retention of the urine caused by enlargement of the prostate gland.

Anteversio usually causes frequent urination in a more marked degree than prolapsus. In this displacement the uterus is generally enlarged and elevated, so that the body and fundus rest upon the bladder and impede its distention.

Retroversion affects the bladder the same as prolapsus, except when the uterus is very much enlarged and is thrown backward and impacted in the pelvis, so that the cervix presses firmly on the urethra. In such cases urination is impossible. Examples of this are seen in retroversion occurring in the early months of pregnancy or after confinement.

Functional derangement of the bladder, arising from the various forms of displacement of the uterus, is characterized by one peculiarity, and that is, that the trouble is aggravated by the patient standing or walking, and relieved by lying down. You can usually tell that the frequent urination is caused by displacement when the position of the patient so affects the symptoms. The exceptions to this rule are very rare, but one of these I related in my previous lecture.

I have observed that patients with anteversion often

* Bichereau *Archives G n ral de M decine*, was the first to give quinine in urethral fever.

suffer from frequent urination, but I have not been able at all times to say whether the trouble was due to the fundus uteri resting on the bladder or to the super-sensitiveness of the whole pelvic organs. I have inclined to believe that the latter was usually the cause.

Having thus briefly disposed of some of the more important functional disturbances of the bladder, I now turn your attention to diseases of the urethra.

Acute urethritis, though not a very frequent disease among women, is a very distressing one to the patient, and often difficult to relieve. In many cases you will find the pathology specific, *i. e.*, due to gonorrhœa; and I would treat this subject as gonorrhœa in women, were it not that it is often difficult to tell a specific or venereal urethritis from simple inflammation of that portion of mucous membrane. There is a difference in history when we can get correct testimony from the patient. Simple urethritis usually comes on gradually, and is preceded by symptoms of uterine or vesical disease; while gonorrhœa comes on rather abruptly, and is preceded or attended by acute vaginitis and vulvitis. The chief symptom is painful urination. Sharp scalding is produced by the urine passing over the tender surface. There is often a frequent desire to urinate, but not so urgent as in cystitis. In some cases the urine is retained for a long time, evidently from a dread of the pain caused in passing it.

An examination of the parts will show signs of inflammation about the meatus, with or without the same condition of the vulva. Occasionally there is a discharge seen issuing from the urethra, but if the parts have been recently bathed this may not be apparent. Introducing the finger into the vagina and pressing upon the urethra from above downwards, the discharge can be started unless the patient has passed water immediately before. The appearance of the discharge resembles that of gonorrhœa in its various stages.

The treatment of acute urethritis, whether specific or not, may be conducted on the same principles as in gonorrhœa in the male, using the same constitutional remedies—local baths, etc. This will suffice in most cases of acute disease; but when it assumes the sub-acute form, or is chronic from the beginning, then the use of injections becomes necessary. Solutions of nitrate of silver, sulphate of zinc, and the like, will answer. You must bear in mind that the female urethra will not hold more than ten or fifteen drops, and if more is used it will enter the bladder, even where very slight force is used while injecting. I use a large syringe, placing the nozzle over—not into—the meatus, and inject slowly and without force a small quantity. When the case is of long standing, and the neck of the bladder appears to be involved also, I use a mild injection of one or two grains of nitrate of silver to the ounce, and inject it through the urethra with force enough to enter the bladder, and let it remain there, to be passed off when the patient urinates. In old cases which began by a severe acute attack, and where the walls of the urethra are very much thickened and the canal contracted, dilatation with bougies does much good. While the bougie is passed once or twice a week, I apply to the vaginal portion of the urethra oleate of mercury or the unguentum hydrargyri. This will often suffice to stop the gleet discharge, as well as remove the thickening of the urethra walls.

Another very troublesome affection of the urethra which results from urethritis, or may appear without any previous disease, is granular erosion, as it is called. The mucous membrane is covered with young, imperfectly developed epithelium; the papillæ are hyper-

trophied and extremely sensitive. This gives rise to the most excruciating pain during micturition, and generally keeps up a distressing tenesmus. This disease is fortunately not very common. Old people are most liable to suffer from it. The diagnosis is made from the history and appearance of the urethra. The treatment which is most reliable is, cauterization of the whole surface. The milder washes and injections do not accomplish much. Pure carbolic acid may be tried first, brushing it over the surface, and repeating it in eight or ten days. This is the least painful application, and answers in some cases. When it fails, solid nitrate of silver should be used; and when that does not suffice, nitric acid or the actual cautery may be employed. Better, perhaps, than these strong caustics, is to dilate the urethra so as to paralyze the muscles, and then touch it with carbolic acid.

Vascular tumor, caruncle, or wart of the meatus urinarius, is an affection which will come under your notice quite as often as any of the urethral diseases. These growths are located in the meatus, and generally on the lower side. They have the bright red and fungous appearance of mucous polypi, such as you may have seen in the nose, ear, or cervix uteri. Sometimes they are pedunculated, but more frequently sessile. They are very tender to the touch, causing the patient much distress when anything comes in contact with the diseased part. The chief trouble is the pain which they cause during micturition. They are easily diagnosed, as a rule. The bright red color of the tumor or tumors—for there are often more than one—contrasted with the normal membrane around, makes detection easy.

The only thing likely to be confounded with them is prolapsus of the mucous membrane of the urethra. This rather rare affection can be distinguished from caruncle by the tumor extending uniformly all round the meatus, and presenting the usual appearance of a mucous membrane in a state of congestion and œdema. It can also, in some cases, be reduced when the patient is lying on the back.

The treatment of caruncle is to thoroughly remove the abnormal part. When they are pedunculated they can be clipped off, and the base touched with caustic to stop the bleeding and prevent regrowth. When they are sessile they should be destroyed by nitrate of silver, nitric acid, or chromic acid. To be able to apply the caustic to the abnormal part, and save the normal portion of the urethra, I have used a No. 10 or 12 gum catheter, having one side cut away. This I introduce into the urethra so as to bring the tumor into the notch of the catheter, and the caustic is then applied. Better still is the instrument recently described in the *Obstetrical Journal of Great Britain* by Mr. Thomas Bryant. It is something like an ear speculum cut away on one side, and answers as a "dilator, speculum, and protector." It is an improvement on the ordinary female urethral speculum.

I have already mentioned prolapse of the mucous membrane, and I need only say here that it is a rare affection, occurring in broken-down constitutions, where there has been pre-existing bladder or urethral disease. I base this statement on one case which came under my own observation. The appearance is that of a uniform, round, red tumor at the meatus, with the opening into the urethra in the centre of it. If possible it should be returned by pushing it back, and then using astringent washes to endeavor to keep it in position; but this, I learn, usually fails, and then removal of the prolapsed portion is necessary. The quickest and best way is to take it off by the galvano-cautery. When this is not at hand the actual cautery

may be employed. The most prominent portions should be touched, which will cause sloughing; and the contraction which occurs during healing will dispose of the superabundant tissue.

I ought to mention polypus of the urethra, which is one of the rare troubles, and may be classed with vascular tumor and prolapsus. No difficulty will be experienced in the diagnosis and treatment of this disease when the tumor is situated at or near the meatus urinarius. When it is situated high up, it may escape notice in the ordinary examinations. When the symptoms point to the presence of such tumor, a small speculum should be used, or the instrument of Bryant already spoken of. When the polypus is detected it should be removed. To do this, however, it is necessary, as a rule, to dilate the urethra. This can be easily and safely done by using sounds or the improved Barnes' dilators.

Recently dilatation of the urethra has been practised very extensively. Dr. Noeggerath, of New York, has not only employed dilatation as a means of examining the urethra and bladder, but also for the purpose of admitting the finger to explore, by the touch, all the organs of the pelvis. He was not the first to dilate the female urethra—that had been done long ago—but he was the first, I think, who dilated it for the purpose of examining the pelvic organs. In the space of a few hours he has dilated the urethra sufficiently to admit the finger, and no very serious trouble followed, which is contrary to what we might have expected. This dilatation of the urethra for the purpose of examination, and also as a means of curing many of the urethral and bladder diseases, is one of the most important improvements in the management of this class of surgical affections. It is to the urinary organs what stretching the sphincter ani is to the surgery of the rectum.

I have only time to briefly notice urethrocele, and refer you to Dr. Bozeman's article on that subject in the *American Journal of Obstetrics* for February, 1871. In his paper you will find a more extended account of the subject than I can possibly give. The pathology given by Dr. Bozeman is as follows: First, the lower portion of the urethra becomes constricted, by infiltration of the tissues outside of the urethral mucous membrane. This causes dilatation of the urethra higher up; and at the same time the muscular coats increase in size. The result is, that the central portion of the urethra being distended, settles down, so that in time the urethra, in place of being a straight canal, becomes triangular, the upper portion being the base, and the central and lower portion (that is, midway between the neck of the bladder and the meatus) the apex. At this dependent portion a few drops of urine accumulate, which also increases the distention, and by its decomposition causes inflammation and ulceration. The urethrocele projects down into the introitus vulvæ, in the shape of a tumor, which may be mistaken for cystocele. In time the inflammatory affection of the urethra involves the bladder.

Among the causes mentioned are injuries during labor, over-exertion, excessive coition, congestion, and inflammation of the mucous membrane. The symptoms (after the disease which began the trouble has subsided) are first difficult, and finally painful and frequent urination. The diagnosis can be made from the history and the presence of a tumor in the introitus vulvæ, and the deflected condition of the urethra.

The treatment recommended by Dr. Bozeman is to tap the urethra at the most dependent portion. He proposes to make an opening through which the urine can pass, and leave it open until all inflammation has

subsided—say one or many months—and then close it.

Regarding this disease I must say, that I have not seen many cases of it, or if I have, I failed to detect its true nature. One case I remember which corresponded to the history of urethrocele, and was no doubt a genuine specimen; but I recollect she got well under treatment, which consisted in dilating the urethra with sounds and washing it out frequently with a solution of nitrate of silver.

Finally, I will mention fistula of the urethra—not the ordinary opening which comes from injury and is described in text-books along with vesico-vaginal fistula, but blind internal fistula. The history of a case will perhaps answer better than a description. A lady had what appeared to be a cyst in the urethro-vaginal wall. Inflammatory action set in; and the pressure of the knife, used to open it in the vagina, caused an opening into the urethra at the same time. The wound in the vagina healed, but the opening in the urethra remained, and pus and urine accumulated in the sac, and a pretty constant discharge from the urethra continued. In another case of specific urethritis, followed by considerable thickening of the urethral wall, a sac or pocket was formed, which filled with pus and urine, and supplied a discharge which was almost as constant as an acute urethritis.

The treatment in both cases consisted simply of dilatation of the lower portion of the urethra with sounds, and washing out the urethra and sac with borax and water. The patients were also directed to make pressure upon the upper portion of the urethra, after urinating, to force out any urine that might lodge in the fistula or sac. One case recovered, and as the other did not return it may have ended in recovery also. In case this method should fail, I think it would be good treatment to make an opening into the sac from the vagina; *i. e.*, make a complete urethro-vaginal fistula, and afterwards close it by the usual operation.

FRENCH MEDICAL NIGHT SERVICE.—To remove the inconveniences and hardships attendant upon night service on the part of physicians, the prefect of police of Paris proposes to establish a service similar to the one existing in St. Petersburg. He recommends the following arrangement, which will necessitate an addition to the expenses of the city of a sum of about ten thousand francs only. In every quarter medical men will be invited to declare whether they are disposed to attend to requisitions addressed to them in the night. The names and domiciles of those who may be willing will be inscribed on an official list, posted in the police stations of the quarter. The person who may require a doctor will go to the neighboring police station, and will select from the list the name of the practitioner whom he desires. A police officer from the station will accompany him to the house of the medical man, will follow the latter to the house of the patient, and will, when the visit is over, reconduct him home. On leaving him he will give him an order on the police treasury for ten francs. According to the pecuniary position of the patient the administration will reclaim the fees paid, or will assume the cost of them.

THE QUOTATION OF PROPER NAMES by French journals is proverbially inaccurate, but the obtuseness which converts the name of Professor John Hughes Bennett into that of M. le professeur Huebbenet is beyond comprehension.—Vide *Gazette Hebdomadaire*, of Oct. 29th.

CASE OF BRONCHOCELE PRODUCING
SUDDEN DEATH BY ASPHYXIA.

By ANDREW H. SMITH, M.D.,

OF NEW YORK.

Surgeon to the Throat Department of the Manhattan Eye and Ear
Hospital, etc.

MARGARET M., aged 16, was sent to me May 10, 1865, by Dr. Janvrin, at that time on duty at the institution of which she was an inmate. Her history was as follows: In August, 1874, at about the time when the catamenia were first established, she noticed that there was a slight enlargement of the throat. This continued to progress notwithstanding the use of iodine, locally and internally, until when I saw her the circumference of the neck was seventeen inches, and the tumor extended from the chin to the sternum, and from the external border of the sterno-mastoid muscle on one side to the same point on the other. She had had for some time an occasional husky cough, and had experienced slight shortness of breath on any occasion of unusual exertion. Menstruation regular.

On examining the tumor it was found to be nearly symmetrical, except that on the right side there was a lobe projecting forward, about the size of half an English walnut. Just above this, and at a point corresponding with the right ala of the thyroid cartilage, was a spot about an inch in diameter, softer than the rest of the growth, and presenting a fine thrill under the finger with each systole of the heart. The stethoscope placed at this point gave a loud blowing murmur, which was also audible, though less distinctly, over the whole tumor. The growth as a whole was rather soft, having about the resistance of a case of simple glandular hypertrophy.

The treatment consisted in the use of the galvanopuncture, which was employed about twice a week. From ten to twenty cells of a Drescher's constant battery were used, each sitting continuing about fifteen minutes. On several occasions the injection of half a drachm of tincture of iodine into the growth was substituted for the galvanopuncture. At the end of a month or six weeks the circumference of the neck was found to have diminished half an inch. At this time I went into the country, and did not see the patient again until September 22, when I was hastily summoned, and found her insensible from asphyxia. I learned from Dr. McQuesten, who was in charge of the case, that there had been a slight aggravation of the symptoms after the treatment was discontinued, but that they were not at all urgent until about an hour before I was called. The patient had had a slight cold, and going out into the cool fresh air of the yard she was seized with a fit of coughing, which in a moment became convulsive, and was accompanied by such extreme dyspnea, that she sank to the ground and became unconscious. She was carried into the house, and laid upon the floor, and Dr. McQuesten was summoned. He came immediately and found her entirely unconscious, the face livid, and the breathing extremely labored. He placed the head in a position to favor respiration, drew the tongue forward, and applied ice to the tumor, with the hope of reducing its bulk by causing contraction of the vessels. But none of these measures were of any avail. The as-

phyxia became more and more pronounced, and a few minutes after my arrival, and a little more than an hour after the commencement of the attack, the patient expired.

It was observed that the moment the action of the heart ceased, the tumor, which before was tense, became flaccid, and seemed to lose considerably in bulk.

At the autopsy, which was made by Dr. McQuesten, the vessels of the neck were found greatly distended, and notwithstanding every care in the removal of the growth a very large amount of blood escaped. The capsule of the gland was found to be blended with the fibres of the sterno-thyroid muscles. The edges of the growth were overlapped slightly by the sterno-mastoid muscles, but not sufficiently to be a source of pressure. The isthmus of the thyroid gland was not hypertrophied to any considerable extent, but the lateral lobes were in contact with each other in the median line as accurately as the two hemispheres of the brain, a few fibres of loose cellular tissue passing from one to the other. Posteriorly, these lobes extended behind the trachea and œsophagus, completely embracing them and meeting each other in front of the spinal column. The trachea was very much compressed from side to side, and its area reduced at least one-half.

A histological examination of the growth was made by Dr. C. S. Bull, who found it to be of the form (denominated by Virchow "struma gelatinosa vasculosa.")

Viewing this case in the light thrown upon it by its unlooked-for termination and the result of the autopsy, let us see what lessons may be derived from it. In the first place, it shows that in a case of bronchocele which is marked by even the slightest degree of dyspnea, this may on slight provocation be increased to the point of asphyxia. In this instance a smart attack of cough was sufficient to congest the vascular growth, which, compressing still more the already contracted windpipe, produced dyspnea, and this in its turn aggravated the congestion. Thus a circle was established, the congestion increasing the dyspnea, and the dyspnea increasing the congestion. Unless this circle could be broken the death of the patient was inevitable.

The lesson from this is, that these cases should not be allowed to go on after there is evidence that the trachea is being narrowed. Shortness of breath on exertion should be the signal for efficient interference to procure a diminution of the tumor. Had the electrolytic treatment been continued in this case it would probably have effected this result. Injections of iodine would also promise well in a case of simple hypertrophy. But if these means did not yield a sufficiently prompt result, I should not hesitate to adopt a plan which I have long had in mind, and which is, to reflect the skin from the tumor at two or more points, and then thrust a galvano-cautery loop into the growth in various directions and leave the resulting tracks to suppurate. This would bring about a prompt reduction of volume, and, judging from the effect of setons, would probably in the end cause the absorption of the entire mass.

But after the asphyxia was developed could anything have been done for the relief of the patient? Division of the sterno-mastoids would have been of no avail, for the counter-pressure was evidently afforded by the deep cervical fascia.

To have divided this with sufficient freedom would probably, in the engorged condition of the vessels, have been attended by fatal hemorrhage; the more likely, as pressure could not have been applied to cen-

trol the bleeding, without at the same time pressing on the trachea. If we could have known that the thyroid isthmus was not involved in the hypertrophy, it would perhaps have been possible, by tying the enlarged superficial veins which crossed the track of the incision, to have reached the trachea without excessive hemorrhage. But we could not know this, and the operation at best would have been a difficult and tedious one, for which there was not sufficient time.

But there is one thing which I regret that it did not occur to us to try, and that is venesection. It is possible that a very copious bleeding might have relieved, in some degree, the pressure upon the trachea; first, by the direct abstraction of blood from the tumor, and secondly, by weakening the heart's action, which was forcing the blood into the quasi-erectile tissue of the gland. The influence of this latter agency was shown by the subsidence of the tumor as soon as the heart's action ceased, but it was then too late to profit by the hint. In fact, it needed this evidence and that of the autopsy to show that the dyspnoea was wholly dependent upon congestion of the growth.

SOME SUGGESTIONS ON THE TREATMENT OF INTERMITTENT FEVER.

By M. A. WILSON, M.D.,

NEW YORK.

WHILE resident physician of St. John's Hospital, Cincinnati, O., in 1857-63, I became familiarized with the following simple plan of treatment of the malarial, intermittent and remittent fevers. I am not aware of it having ever been published, nor do I hesitate to say emphatically that it is much superior to any other mode of prescribing quinine, for the remedy is our same old sheet-anchor, only a little difference in the administration of it.

We will suppose the patient to have the first attack of ague; chill, followed by fever and sweating-stage, to take place, for instance, at three o'clock P.M. During the *sweating* stage of this paroxysm, not less than fifteen (better twenty) grains of quinine should be given to (an adult) in powder or solution, in preference to pill form, unless freshly prepared.

If the bowels and stomach are disordered, or any tendency to constipation exists, an active purgative, such as two or three pill cathart. co., should be administered, either at once or at night.

Until the next paroxysm, which we will further suppose to occur on the second subsequent afternoon (tertian type), some such prescription as the following:

R. Quinine sulph. ʒ ss.
Acid. sulph. aromat. (or dil.) . . . ʒ i.
Syr. zingiberis ʒ ss.
Aque cinnamom. ad. ʒ iiij.
M.

S.—A dessert-spoonful every three or four hours.

Before the next expected paroxysm, this prescription (twelve doses) will probably have all been taken, and very frequently this treatment is sufficient, there being no further "chills;" but, not knowing positively whether there will or not, it is advisable to anticipate, and give, *one hour* before the next expected attack (which, in our supposed case, would be about 2 P.M., forty-eight hours after the first attack), not less than ten, preferably fifteen, grains more of quinine.

This amount (the first dose of twenty, in the prescription or mixture thirty, and the last dose of fifteen,

making in all sixty-five grains), in the majority of cases most generally completely and permanently "cures" the patient, who may never again suffer from ague, unless peculiarly and constantly exposed to malarial influences.

This we cannot say is the result obtained by any means through the ordinary mode of prescribing quinine, viz., two or three grain pills, three or four times daily; this mode of administration merely sufficing to check the disease for two, three, or more weeks after the patient ceases to take it.

Even after such small doses have been taken for weeks at a time, the "chills" invariably recur (there being a longer or shorter interval of time) until the patient is discouraged, despondent, exhausted, suffering from all the horrors of what is commonly called "dumb-ague," and willing to buy and try any patent nostrum.

I do not wish to be too positive, but I do not think that I have ever treated the *same* patient a *second* time for malarial poisoning, after the adoption of this method of treatment, although I wish to be understood as referring chiefly to recent attacks, "acute" ague—when it first begins, or as near that time as possible.

The great difficulty in chronic cases, the dumb-ague, is to ascertain the times of the paroxysms, as they seem to occur irregularly, *any* time, and the case is "mixed;" so that we can scarcely decide when to give these full, definite doses.

Besides, so much quinine has been already administered in long-continued small doses, many of these patients more or less constantly experiencing its peculiar cerebral effects, that a further amount is useless; the time has passed for trial of the above-mentioned plan, and we must prescribe other remedies.

Owing to the cachexia and debility, I usually continue the use of a small quantity, say five grains daily, in conjunction with iron, as well as the vegetable bitters, mineral acids, etc., according to, and as long as the indications may warrant the use of tonics.

In chronic malarial poisoning, after quinine has been thoroughly and fully tested, we must treat our patients somewhat empirically, and employ such remedies as are termed blood-depurants.

The various alkaline or other diuretics, cholagogues, as calomel in minute doses, blue mass, podophyllin, ipecac, conium, taraxacum, combining some of the latter drugs with arsenic, nux-vomica or strychnia, belladonna, aloes, gentian, etc.

Among other anti-periodics, I may mention piperin, which is much valued by many practitioners, sulphate of beheria (this being at present, however, rather discarded); and my esteemed friend, Prof. M. A. Pallen, M.D., of this city, speaks most highly of the picrate or carbo-zotate of ammonia, one-third grain doses, combined with quinine, in pill form.

As the details of an attack of ague are not sufficiently interesting to occupy much time or space, I will merely mention one case from my note-book, which occurred sufficiently long ago to warrant us in believing it to be "cured."

In April, 1872, I was called to see Major B., a gentleman who had suffered from an attack (first one) of ague six weeks previously, in Galveston, Texas.

The physician there had prescribed sugar-coated, two-grain quinine pills, one four times daily, which had been taken for about a week.

Leaving that city during the following week, he had just arrived in New York when another paroxysm came on.

When I saw him, Friday, 2 P.M., he was in the first

(cold) stage, and I prescribed nothing for *immediate* use whatever, but ordered twenty grains of quinine to be taken during the sweating stage, and ten grains of blue-mass at bed-time, followed with a bottle of citrate of magnesia next morning. This being of the tertian type, and as the next chill was expected on the following Sunday p.m., I prescribed the mixture as detailed above, to be taken during the interval, and fifteen grains more for Sunday, 1 p.m., anticipating the attack one hour. On Sunday *at no time* did he experience any symptoms whatever of a return of his "ague-fit," but still he took the last dose.

Since that time, now more than three years, he has travelled far and in all directions, and has been much exposed to the influence of malaria, but he has never suffered in the slightest, nor had any symptoms of ague.

Without doubt the amount of quinine he had taken before I saw him was of material benefit and assistance in the cure; but what I wish especially to refer to is not the *amount* so much as the *mode* and *time* of taking the antidote.

Had he in his second attack (the one for which I treated him) again begun the use of the "two-grain pills," temporary benefit would have resulted. But the controlling influence of the quinine taken in this manner would not have been sufficiently great to have prevented the recurrence of several subsequent attacks, each one probably lighter or of briefer duration, until, owing to its constant use for several weeks, sufficient had been taken, and the paroxysms would again temporarily cease.

The patient, now somewhat relieved, and weary of medication, would most likely put all aside entirely, until, after a variable lapse of time, his old enemy, "the chills," would again be upon him. Thus, in this irregular, discouraging manner, these attacks would recur again and again, when sooner or later quinine would entirely lose its controlling power (if in fact it was exercising *any* influence in such a case), and the patient be "only one more" miserable case of chronic ague; constantly suffering from slight chills, transient fever, headaches without cause (at least unrecognized by him), more or less nausea, pains in the head and back, with anorexia, lassitude, low spirits, etc.; broken down in mind and body, saturated with malaria, and the "antidote" (as I believe it to be when properly used) no longer of benefit.

This slight description is not overdrawn; it could be lengthened: and yet, as well as I can ascertain, my professional brethren almost universally treat malarial fever with quinine in small doses (one, two, or three grains several times daily), continued a longer or shorter time; whereas, if two or three (sometimes one is sufficient) *full* doses were administered (the first during sweating stage when that is pronounced, owing to the greater rapidity in the absorption and consequent effect of the remedy), combined *with* the usual mode of small doses frequently, as in above-described mixture, these ague cases would have but a brief existence, merely because the quinine is then employed *as* an antidote, enough given *at once* to promptly overwhelm and overpower the poison, as we would in any other case of poisoning; as in the free use of hydrated peroxide of iron in arsenical poisoning.

No. 12 E. 38th STREET, N. Y. CITY.

A MONTREAL DOCTOR has just sued his landlord for twenty thousand dollars damages for illness caused, he alleges, by the unhealthiness of the house in which he resides.

Progress of Medical Science.

PROGRESSIVE PERNICIOUS ANEMIA.—The last number of the *American Journal of the Medical Sciences* contains a long article on the above interesting disease, by Professor William Pepper. The paper is rendered especially interesting by an endeavor to intimately associate several of those diseases which depend upon defective blood-development, and which have been variously denominated as idiopathic, essential or malignant anemia, or grave forms of chlorosis, leucæmia, pseudo-leucæmia, adenia, lymphadenoma, or Hodgkin's disease, and progressive pernicious anemia. The name progressive pernicious anemia was first applied by Biermer, of Zurich, to a peculiar form of anemia which began insidiously without any distinctly assignable cause, and gradually progressed to a fatal termination. The disease was characterized by diminution of the red globules of the blood without increase of the white corpuscles, and was accompanied with pallor of the surface, but slight or no emaciation, failure of the heart's action, with anæmic murmurs and passive dropsy. Late in the course of the disease ecchymoses appeared occasionally underneath the skin or in the retina, with hemorrhages from the nose or kidneys. There was no affection of the spleen or lymphatic glands. The only organic lesion found post-mortem was fatty degeneration of the heart and of various other organs. Biermer wrote under the impression that he was describing a new disease, and this impression would appear to have been generally entertained. Pepper, however, has collected a number of cases which had been previously recorded, which he regards as relating to precisely the same disease as that described by Biermer, and indicate, as he thinks, that the affection is less rare than has been supposed. It is claimed, indeed, that the same disease was clearly delineated by Addison, and that it was the study of this affection which he described under the name of idiopathic anemia, which led him to investigate that other form of anemia which is associated with bronzing of the skin.

Furthermore, it is claimed that this idiopathic or progressive pernicious form of anemia differs from the disease known as pseudo-leucæmia only in the fact, that the latter disease is associated with lesions of the organs supposed to be connected with the formation of the blood—the spleen, the lymphatic glands, and the medulla of the bones. At about the same time that Addison's investigations were made, Virchow and Bennett called attention to leukocythæmia or leucæmia—a disease marked by great increase of the white corpuscles of the blood, together with a diminution of the red globules. Three varieties of this disease were described, according as the chief lesion existed in the spleen, lymphatic glands, or marrow of the bones, viz., splenic leucæmia, lymphatic leucæmia, and medullary leucæmia. Subsequently a form of cachectic anemia was described, in which similar lesions were found, but without increase of the white corpuscles. In contradistinction to the above, therefore, this disease was known as splenic, lymphatic, or medullary *pseudo-leucæmia*.

Now, inasmuch as all of these forms of disease evidently depend upon some defect in the blood proper, and are essentially due rather to the absence or destruction of the red globules than to the increase of the white corpuscles, it is proposed to class them alto-

gether under one general term, and for this the writer suggests the word *anammatosis*. Instead of regarding leukemia as the type of these diseases, he prefers to consider the increase of the white corpuscles as rather an accidental or non-essential condition, the presence of which may be expressed if desired by the prefix "*leucocytic*."

Full reports of three cases of progressive pernicious anemia are communicated, and afterwards the various points connected with the etiology, course, pathology and treatment of the disease are discussed in detail. In the third case related by Pepper the autopsy revealed very interesting changes in the medulla of the bones, which consisted in extreme hyperplasia of the marrow with production of lymphoid cells, and corresponded to the condition described by Herrmann, Ponfiek, Mosler, and others as found in some cases of leukemia. In view of this case the writer inclines to the opinion that idiopathic or progressive anemia is identical with the medullary form of pseudo-leukemia.

The article closes with the following conclusions:

1. Progressive pernicious anemia is identical with the idiopathic anemia of Addison, and is in no sense a new disease.
2. It is in reality the medullary form of so-called pseudo-leukemia.
3. As the primary and essential lesion in this and the analogous conditions (leukemia and pseudo-leukemia) appears to be an affection of the chief blood-making tissues—spleen, lymphatic glands, marrow of the bones—causing defective elaboration of the blood, it seems proper to select some name that will indicate this fact, as *anammatosis*.
4. The changes in the blood consist of great reduction in its mass, with extreme diminution in the proportion of red globules, without increase in the white corpuscles. There are probably also changes in the vital properties both of the red and white corpuscles.
5. The other lesions, chiefly fatty degeneration of the heart and other organs, passive effusions and hemorrhages, are secondary, and depend upon the blood changes.
6. The symptoms are explicable, in great part, by the state of the blood and the condition of the heart.
7. The disease, when once fully established, appears to be invariably fatal.
8. The remedies which appear to afford most prospect of relief, are cod-liver oil, arsenic, and phosphorus.
9. Transfusion is only capable of doing temporary good.
10. This operation is not free from grave danger, owing to the feebleness of the heart and the small amount of blood in the vessels; and, in order to be safely employed the amount of blood injected must be very small (f. 5 iii.), it must be introduced slowly, and the operation must be repeated at suitable intervals. It adds to the safety of the operation to inject the blood into a small artery instead of a vein.

SYPHILITIC CHANCRES OF THE BREAST.—Dr. R. W. Taylor reports three cases of primary syphilitic affections of the breast, giving a minute description of the peculiar appearances of the initial lesion in this situation. The three cases represent the three varieties of syphilitic chancre of the breast described by Fournier. These varieties are the indurated fissure, the ecchymatous form, and the superficial erosion. In Taylor's first case there were several indurated fissures about the nipple, all of them having elevated pinkish-gray edges, with a deep sulcus between of a deeper reddish color, from which a thin, scanty secretion was exuded. The ulcers were exceedingly sensitive, and

when pinched between thumb and forefinger a dense induration was perceived. In this case the indurated pectoral and axillary glands could be distinctly felt, though Taylor observes that where lactation has been prolonged, and the breasts are flabby, the condition of the pectoral glands may be obscured by the presence of thickened lactiferous ducts and localized hard spots of adenoid tissue.

In the second case a thin brownish-green crust appeared, which was loosely adherent, and when removed revealed a shining grayish-pink ulcerated surface of great smoothness. The edges were not elevated, but when the tissues beneath the ulcer were pinched between the fingers a distinct induration was felt, and the peculiar blanching of the tissues, often observed in hard chancres, was produced. The encrusted condition of the ulcer was ascribed to the fact that the mother did not nurse her child upon that side.

The last case—the instance of superficial erosion—was characterized by the appearance of several excoriated spots, the largest being about a line and a half in diameter, which were slightly elevated above the surrounding surface, were perfectly smooth, and showed no sign of granulations. The margins were sharply defined. The secretion was scanty and serous. "The appearance was precisely as if, owing to hyperæmia, the very superficial layers of epidermis had been cast off, and the affected tissues slightly elevated." The syphilitic infiltration seemed very scanty and superficial, and the induration was inappreciable. In other instances of this variety of chancre the writer had observed more marked induration.—*Archives of Dermatology*, October, 1875.

ANGINA PECTORIS.—Dr. Hamilton Osgood, of Philadelphia, contributes a paper on "Angina Pectoris," to the last number (October) of the *American Journal of the Medical Sciences*, with detailed reports of five cases of the disease, together with copious references to the literature of the subject. The writer regards the disease as a neuralgia, which is not necessarily dependent upon cardiac disease, and is not, as maintained by many writers, confined to middle and advanced age. O. is inclined to embrace the view of Laennec, viz., that the neuralgia may originate in different nerves, and yet give rise to the same train of symptoms. Thus the original seat of the disease may be in the pneumogastric, or the cardiac portion of the sympathetic, and the brachial plexus become implicated secondarily, by sympathy. It is thought that, when the affection is associated with organic disease of the heart, it should be regarded rather in the light of a mere coincidence, than as properly a symptom of cardiac disease. The existence of pseudo or simulative attacks of angina is denied. It is supposed, with Romberg, that hysteria may give rise to true neuroses, among which is angina pectoris. Attention is called to a symptom of angina, not hitherto described, namely, an inequality of the radial pulses in the two arms. During the paroxysm, and, indeed, in some cases, as a premonitory sign of its advent, Osgood has observed that the left radial was markedly smaller than the right,—indicative, it is supposed, of increased arterial tension on the affected side. The remedy on which the writer mainly relies is the nitrite of amyl. He begins with one or two drops, and increases the dose gradually till a flushing of the nose is produced. Guided by this symptom of its action, he believes the remedy may be used with perfect safety. As a rule he has found it unnecessary to exceed eight drops; but in one case as much as a drachm was administered before the desired effect was obtained.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

W.M. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, December 4, 1875.

HOSPITAL MANAGEMENT.

THE question of hospital management in this city, especially that phase of it which relates to the relative rights of managers and the medical staff, has been receiving a very animated discussion. What has been styled the Presbyterian Hospital affair has been the pivot around which most, if not all, of the interest in the subject has revolved. From this apparently insignificant starting-point—from the mere failure to re-elect four gentlemen of the medical staff—from what at first appeared to be a private affair with the board of managers—the matter has magnified itself into one of principle, and has assumed such proportions that a mass meeting of the profession has been held for the purpose of giving a public expression of opinion.

It has been our aim from the very commencement of this trouble to give both parties a fair hearing, and to found our conclusions upon the bare facts presented. We believe that the greater part of the testimony is before the jury of public opinion, and the case, so far as it can be presented, is ready for a verdict.

As far as we can judge, both parties still maintain their original attitude. The Board of Managers of the Hospital maintains its right to drop any member of the medical staff it sees fit, without showing cause, and a goodly majority of the profession deny this right. In one sense both parties are right, and both are wrong. As often happens under such circumstances, there is some middle ground of opinion upon which differences can be compromised respective rights adjusted, and proper preparations made for unprejudiced judgment. The more we run into extremes, the farther do we stray from the truth, and less likely are we to mete out strict justice. Ill-tempered speeches, fiery denunciations, and unmanly vituperations are not always the best means to expose error, force conviction, or bring about repentance; neither is dignified silence, an apparent indifference to public opinion, and a studied refusal to explain the

cause of action the best means to answer argument. The defiantly belligerent attitude of both parties is to be deplored, if for no other reason than that it has prompted the utterance of threats to each other, which, if they are not shameful, are at least puerile. The extremists on one side threaten to break up the hospital, to force medical men to resign their positions therein; and the extremists on the other side connive to destroy the chances of any who have already resigned, or who may in future resign, from the hospital in question, for any other similar appointment in the city. If this is the way to discuss a principle, a new system of logic is needed.

How can we get at the right of the matter? Probably in no better way than by studying the facts of the situation, and examining the claims of each party in the strife. In the first place the managers have the undoubted right to nominate whom they please for the office of medical attendant. If this is denied, then we are at a loss to determine how any of the staff gained their positions at all. The very fact of holding such positions is an acknowledgment of this right. If there is any doubt in regard to the free exercise of this prerogative on the part of the appointing power, the medical profession as a whole are very much to blame for it. The history of the struggles for hospital appointment, on the part of the medical men, carries such a conviction on its very face. In view of the existing system of hospital appointment, the hope of any radical change in regard to it seems a long way off.

In the next place, the managers claim the right to decline to re-elect any one or more of those who have already served the hospital. This is hardly open to question, in view of a by-law upon the subject to which each member of the medical staff is supposed to subscribe. So far, then, the case seems clear enough. The board has by such means ample powers for self-protection, in fact it has everything in its own hands, to do what, according to its interpretation, is "for the best interests of the hospital." This being the case, it becomes them to use extraordinary discretion in their rulings; in fact, knowing that they have an absolute power, if they are capable of erring at all, the error should be on the side of mercy, if not on that of justice. They certainly can lose nothing by giving their dependants the benefit of a reasonable doubt. In the present instance, as any one can see, a grievous mistake has been made. Instead of being magnanimous, the majority of the board has been stupidly intolerant, and has laid itself open to the criticism of all fair-minded men. The members exercised their right, it is true; but they did it in a peculiarly offensive way to the profession—by refusing to give any other reason than that of a mere whim. In fact, it is authoritatively asserted that no charges were brought against any of the gentlemen deposed, and while going farther and asserting that they are in their opinion capable men for

the positions, they fail to re-elect them. This, to say the least is quite an original way of proving their fitness to judge concerning what should be the real interests of the institution which they assume to control. The gentlemen of the staff who were thus deposed have a perfect right to protest against such a course, and on a question of principle the profession is right in upholding them. As far as we can learn, this protest was respectful in its tone, and was entitled to a respectful answer. If the latter had been vouchsafed, all would have been well. Instead of that, however, it would seem that the board chose to hide its wrong-doing behind the cloak of its official dignity.

We have always believed, and still believe, that the board should have given these gentlemen some reason for the course adopted. It is true no by-law compelled them so to do, but ordinary courtesy had, if possible, a still higher claim upon them. There would have been no violation of any by-law in asking these gentlemen to resign before the election, and giving the reasons, if they had any, for such a request. But, as every one knows, this was not done. If there was any disagreement in regard to the administration of hospital affairs, as has been intimated by one of our correspondents, this was a matter very easily settled. In fact, the whole profession would be interested in the solution of the question of the relative authority of executive officer and medical attendant. This is still a problem in hospital management, and the managers of the Presbyterian might have given themselves the opportunity of solving it for all time, and establishing a brilliant precedent.

The excuse for the action of the managers which has been offered by our correspondent in the present number is one which the medical profession will hardly accept. Any and every medical board has a right to elect its own presiding officer, and if it be true that because this board did not elect the President chosen for it by the benefactor of the hospital, then the excuse for deposing the independent voters is worse than the act itself.

The mass meeting of the profession which took place on the 30th ult., and to which allusion has already been made, was in every way a success. The proceedings throughout were dignified and calm, and cannot fail to carry with them the full weight of influence desired. The resolutions which were adopted, and which we publish elsewhere, were temperate in the extreme, and not only reflect credit upon the discretion of those who framed them, but unequivocally set forth the justice of the principles which they advocate. We do not see how any unprejudiced medical man can fail to endorse them.

No one can suppose for a moment that the board had not some reasons for dropping four of the staff; but why, under existing circumstances, they do not see fit to explain such reasons, it is certainly very difficult to understand. Their persistence in refusing forces the

conviction that they either intend to outrage all notions of even ordinary justice, or else are fearful that their method of managing the hospital will not bear honest scrutiny. The sensitiveness concerning professional pressure is of itself a confession of weakness. This was quite manifest at the recent meeting of the board, when a committee appointed for the purpose of investigating the matter reported in favor of reinstating the four medical men who had been dropped. Not only was the report not received, but the members of the committee were rebuked so soundly for their convictions, that they at once resigned all connection with the board. As a result of a misunderstanding of what constitutes the justice of giving a reason for virtually dismissing four gentlemen from the medical staff, five members of the said staff and five members of the board of managers have resigned; and yet the board as a whole still maintains its dignified silence. On this point of issue it was time for the profession to express an opinion, and it is a matter of congratulation that it has been done so thoroughly and so satisfactorily in the resolutions adopted at the mass meeting in question. It is hardly to be expected, under the existing circumstances, that the managers will take any more notice of the protest than it has of former ones of similar import; but they take their own responsibility in ignoring what every one else would consider the reasonable claims of fair play. With them the matter may rest where it is, but with other boards of management the expression of professional opinion in regard to the rights of medical men will doubtless be heeded. If such be the case, the discussion of the Presbyterian Hospital affair will not be in vain.

The suggestion in the resolutions regarding medical representation in the board of managers, it is perhaps needless for us to say, in view of what we have already written upon the subject, meets our hearty approval.

SUBSTITUTES FOR PATENT MEDICINES.

OUR correspondent from Portsmouth, in referring to the relations between physicians and pharmacists, very properly condemns the patent-medicine trade. The remedy which he proposes, however, is not much better than the disease. It would certainly be better to substitute harmless articles for the questionable compounds which make up the quack nostrums, but why is it necessary to use any of these medicines at all? Is it not opening a wide door for fraudulent dealing with the medical profession, by giving counter-prescribing an air of respectability which it does not deserve? In our opinion there should be no compromise with quackery in any shape. The pharmacist should make it a matter of principle to discourage the use of nostrums by every means. This he can never do, if he attempts to meet deception on the middle ground of an expediency, to compromise with quackery in the attempt to improve upon it. The apothecary can al-

ways be safe in warning every one against the use of patent medicines at all times, to all men, and under all circumstances. By so doing he performs a conscientious duty to himself, discharges an obligation which he owes his customer, and deals justly with the medical profession. We hope that the druggists are ready for this question.

THE MEDICAL CENTENNIAL.

We are glad to learn that there is prospect of hearty co-operation, on the part of representative men of the profession in this city, in the plans for the International Medical Congress at Philadelphia in 1876. We have earnestly advocated the desirability of such a conjunction of forces to accomplish so happy a result, and have a satisfaction in the consciousness that we may have aided, even in slight degree, to foment this kindly feeling by pointing out to the profession, here and elsewhere, how necessary it is that Philadelphia, the recognized centre of Centennial entertainment, shall be properly seconded in her well-devised programme.

Reports of Societies.

NEW YORK MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

Stated Meeting, November 12, 1873.

DR. E. R. PEASLEE, PRESIDENT, IN THE CHAIR.

ON CERTAIN POINTS CONNECTED WITH THE NERVOUS SYSTEM OF CHILDREN.

THE topic selected by Dr. Jacobi for consideration, under this heading, was the relation that exists between the sexual organs of children, both male and female, and the nervous system, but especially with reference to reflex movements, and paralysis from genital irritation. This subject is not entirely new, but has been brought into special notice of late by the reports of cases by Drs. Sayre, Otis, and others. Both American and European writers have, some years since, alluded to the unexpected influence which abnormal conditions of the sexual organs may have upon the whole nervous system; such as the reflex neuralgias of various names. It should also be stated that whenever debility or other general influence, acting in any part of the body, so as to produce an effect upon the system, we should expect less of unilateral paralysis than symptoms of a general character. For example, irritation in the small intestines of children does not develop, as a rule, unilateral disturbances, but the symptoms will be rather those of general convulsions.

There can be no doubt but that irritations about the genital organs of children have a wide-spread influence; but the question is whether, in all the cases reported in our journals as illustrations of the effect of irritation of the sexual organs, this irritation as such explains all the symptoms. Reference was made to the case reported by Dr. J. H. Hunt, in THE MEDICAL RECORD for Oct. 16, 1873, as one of the cases of paralysis

due to *nothing else except adherent prepuce*, and the so-called irritation dependent thereon. To what extent this is true in the case referred to, cannot be shown from the language of the article itself; and a number of these cases which have been reported as those of reflex irritation and paralysis, dependent upon similar causes, adherent prepuce, etc., are of the same indefinite character. One of the defective points in these histories is the neglect to mention anything concerning the habits of the children. Absolutely nothing has been said as to whether, in consequence of the irritation of the glans penis, masturbation was present or absent.

It was to this subject—the effects produced upon the nervous system of children by the habit of masturbation—that the doctor directed the attention of the Association.

Before doing so he remarked, that the question of paralysis dependent upon irritation of the glans penis and irritation of the genito-urinary organs in general, is now less settled than ever. It is a peculiar fact that a large number of these cases which have been mentioned in older and more modern literature have to do with irritations and diseases of the genital organs, but just in this field of investigation it has been shown that there is no reflex disease in the question. Post-mortem in a large number of these cases has shown that they were not reflex cases, but that they were the result of disease creeping upward, along the nerves of the spinal cord, and are cases of extensive neuritis or even myelitis. Thus in all these cases, and the number is not small, it must be stated that what has been taken as reflex paralysis was evidently the direct result of inflammatory processes in the spinal cord. Probably in a large number of the cases which have been reported as reflex, there is more or less general or a localized myelitis, and there is behind this, as a cause, masturbation. The results of masturbation in the adult are sufficiently well known and require no further mention in this connection. The results of the habit are the same in infancy and childhood as in the adult, and the habit is not an infrequent one. The doctor remarked that he had had opportunities to see children, both male and female, engaged in the habit, and has had the reports of mothers and attendants who have observed the fact as soon as their attention had been drawn in that direction.

The attacks, for they may be called so, of masturbation will be frequently repeated in the following manner:

A boy or girl at play on the floor; they usually prefer the hard floor, and sometimes will select it in preference to a soft cushion or mattress. All at once they get quiet, cross the thighs, look a little pale in the face, soon become flushed, start up, remain a little immovable, eyes start now and then; they become flushed and excited, and afterwards exhausted. Such attacks have been reported to him as occurring a number of times during the day. A number of cases have been reported to him where the children were closely watched, and seen playing with the genital organs, especially boys while in bed; and not only play with the penis, but finally erect it, and at last succeed in squeezing a small amount of liquid from the orifice of the urethra; and that this occurred just at the time the face became flushed and the eyes started in their sockets. The results of this habit in children are about the same as in the adult, as far as the languor and general irritability of the nervous system are concerned. Such children are irritable, frequently a little bloated; have that peculiar shyness which is present in adults when addicted to the habit; have a peculiarly

sallow skin, and the sebaceous follicles are exceedingly well developed.

The sebaceous follicles in the skin of the infant are very large, and when about one year old they get smaller, but when this habit is contracted these follicles remain enlarged, especially about the face. Probably a great many of the comedones seen upon the face of adults are the result of masturbation. Not all examples of this condition are due to this cause, but whenever such a face is seen it reminds one of masturbation, and probably in very many instances they are due to the influence of this habit. In boys affected by such habits erection of the penis, especially in the beginning, is a very common symptom. Now and then a case will be found which may be recognized by a simple inspection of the penis. When the habit has been continued for some time the glans becomes enlarged, looks irritated, is reddened, and the prepuce is swollen. It has been stated that the same condition is sometimes seen about the genitals of girls, perhaps more frequently than in boys, and that there is a free secretion from the Bartholin's glands and muciparous follicles about the orifice of the urethra. The labia majora also will be very large, and the clitoris is almost invariably enlarged. It is said that there is a peculiar redness of the passages which can be easily diagnosed from the redness of the mucous membrane of the vagina, which is so frequently seen in the cases of leucorrhœa occurring in small children.

What is the cause of masturbation in little children? The cause is always an irritation, and this may be absolutely external, or it may be internal. External irritation is illustrated by direct irritation of the genital organs, especially of boys, by nurses and servants.

In this way the habit is contracted, and in them continued. Another external irritation in boys of eight or ten years of age, is horseback riding.

Sleeping in hot feather beds and sitting upon soft-cushioned sofas is another external irritation. Another cause, unless great care is taken, is placing boys in pantaloons too early. The doctor brought this forward as a cause, for several reasons, namely:

Previous to wearing them the genital organs were kept cool, but the pantaloons press the organs to one side and thus they are kept overheated. In addition, the sudoriparous glands in that region are more or less stimulated, and sometimes considerable moisture is generated. Moreover, when the child desires to urinate, it frequently takes him a long time to get the penis into proper position, and not unfrequently he will be assisted by willing playmates in so doing. All these things it was believed had much to do with establishing the habit, and it occurs in this way much more frequently than most of us are aware.

There are local irritations which are the result of anomalous development. In Dr. Hunt's article adherent prepuce was the ascribed cause of the paralysis. In determining to what extent such effect follows such a cause, it should be stated that in fetal life the prepuce is very adherent to the glans penis. A large number of new-born children exhibit a continuation of the adherent prepuce. As long as it is adherent uniformly for one-fourth or one-third its entire extent, it is probable that no harm will follow. But in those cases where the agglutination is prolonged and pouches are formed behind such adhesion, where copious collections of smegma may occur and get rancid, and urine collect and get acid, a local irritation of the glans penis will result, and give rise to repeated attempts on the part of the little sufferer to get rid of the irritation by pulling at the organ, and in this way the habit of masturbation may be con-

tracted. The same thing may be said with regard to the vaginal canal, when as a local irritation we have a leucorrhœal discharge, which is of such frequent occurrence in little girls. It is the irritation behind the leucorrhœa that gives rise to the habit. An occasional source of local irritation is worms in the rectum. Exposure to cold, as sitting upon cold stools, and the use of coarse sponges or coarse towels, are additional sources of external irritation. Catarrh of the bladder, and calculi in the bladder, ureter and kidney, were mentioned among the sources of irritation. The doctor had found out of forty autopsies in children, six cases in which renal calculi were present. This was not regarded as anything like the truthful ratio; but probably it can be said with truthfulness that in six out of a thousand cases renal calculi will be found in children. There is a large number of medicinal agents which have the power of producing considerable irritation upon the kidney, and when being administered the irritating effects of these drugs should be carefully watched. Notable among these drugs are nitrate of potash and chlorate of potassa, especially the latter. This is a remedy much in use, and it can be easily proved that the kidneys, more than the stomach, will be the first to suffer from the detrimental influences of the drug. When large doses are given, congestion of the stomach and kidney will be produced. A single large dose of chlorate of potash has produced a diffused nephritis, and death from uræmia. In this connection the doctor referred to a case in his own practice, where one ounce of *chlorate of soda* was taken, and the patient died from uræmia. What shall be done for the children, as far as masturbation is concerned?

They are irresponsible, and must be controlled and frequently forced. Circumcision is absolutely essential. Whether the symptoms are cured from the fact that the phimosis which required it is relieved, or whether it arises from the fact that the children are cured of masturbation, is a question. Sometimes it is simply a constipation that causes irritation of the genital organs in children. Constipation in the adult may be the cause of seminal emissions, and very frequently is an important factor in the treatment of such cases. In like manner it must be carefully guarded against in children.

These children should be well employed. They should not be placed in bed until the time arrives for them to go to sleep; and they should be taken up early in the morning, put in a bath, afterwards dressed, and set to work at once.

Can remedies do anything in the treatment of this habit?

Bromide of potassium is serviceable in preventing children from masturbating during the intervals of sleep, and also to procure sleep. Alkalies may be used to the extent of relieving what little catarrh of the bladder may be present. To diminish the general irritability of the parts, lupuline and camphor are of service. Strychnia will be beneficial in many cases, as it is a generally useful remedy in all forms of nervous disease caused by masturbation, either general or local in character; and marked either by symptoms of partial paralysis or symptoms of irritation.

Hypochondria, when it occurs in children, was believed always to be due to masturbation. Epilepsy and chorea have been produced by the habit. Local symptoms of debility are essentially those of more or less localized paralysis. Symptoms of local irritation are much more frequent. A peculiar *hysterical cough*, such as heard in hysterical females, is occasionally heard among boys and girls, and in a large number

of cases can be traced to masturbation as the cause. The doctor then related two cases, both occurring in boys, in whom the hysterical cough was a prominent symptom. *Hemicrania* was mentioned as a disease not infrequently found in children 8 or 9 years of age, as well developed as in the adult, and produced by self-abuse. Iron and belladonna are serviceable in the treatment of this symptom.

Another symptom found occasionally in children 6 or 7 years of age is *neuralgia about the joints*. This is much more frequent than has been observed in former years. The knee-joint is very frequently involved, especially the internal condyle of the femur; also the styloid process of the ulna, and very frequently the vertebral column. Excessive masturbation is the cause not infrequently in these cases. Some say that spinal congestion is present; others, that the condition in the spinal canal is one of anemia; others, that it is a neuralgia of the skin, bones, and periosteum, etc., etc. Strychnia was recommended in these cases of so-called spinal irritation, not so much with the view of overcoming the anemia as for its stimulant effect upon the nervous centres.

Hysterical paralysis was mentioned as occurring in children from 5 to 10 years of age, and the case of a girl of about that age recited. The universal paralysis would pass off in the course of a day or two, and the patient would then feel as well as ever. In this instance there was a history of masturbation extending over several years. Dr. Jacobi then referred to cases reported by different authors of the occurrence of hysteria in children.

DR. A. C. POST mentioned a case in which marked hysteria manifested itself in a girl aged 9 years, and in whom the passage of large quantities of limpid urine was a prominent symptom.

DR. JACOBI mentioned a case of orgasmic spasm that had been brought to him as a case of epilepsy. In some of these cases it requires the greatest care and caution to find out what their true nature is, and to determine whether masturbation is present.

DR. LEAMING mentioned incontinence of urine as a symptom in children given to masturbation. In some of these cases the application of caustic to the prepuce and clitoris, just sufficient to make them a little tender, had been attended with much benefit. In the asylum with which he is connected, it had also been observed that a change from a stimulating animal food, beef and mutton, had been followed by good results, and that by so doing the habit was more easily managed. The habit has been found to be excessive among the children, and when one bad child is admitted, it requires the closest watching to prevent its spread among the other children. The habit of wetting the bed and clothes has been broken up in the institution by watching the children, and breaking up the habit of masturbation. These were children from 2 to 7 years of age.

DR. PEASLEE remarked, that with regard to irritations of the glans penis by adherent prepuce in young boys, there is a very important distinction to be borne in mind. If it be the fact that such adherent prepuce together with the accumulated smegma within the prepuce and around the glans, is not sufficient to produce the symptoms referred to *without* the masturbation, it is important to be determined, for in such case the operation of circumcision is not sufficient to effect a cure. On the other hand, if that state of things will induce the habit of masturbation, it is also important to be determined. But in either case the child is not cured by the operation.

DR. GIBNEY inquired how long after birth the phimotic condition present in foetal life remained?

DR. JACOBI replied that it may remain for months and sometimes for years. In a very large percentage of those circumcised, the operator is obliged to tear a portion of the prepuce from the glans penis.

When the agglutination is simply epithelial, it will remove itself usually within a few months or at most within a few years. But some cases are more than this, and are real instances of agglutination.

DR. MESSENGER regarded the question of the use of feather beds and cushioned chairs as one of importance, and too much overlooked in the management of children. Their influence is detrimental.

Correspondence.

THE PRESBYTERIAN HOSPITAL AFFAIR.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—I notice in your valuable paper of date of November 27, 1875, No. 265, two articles—one a communication from an ex-appointee of the Presbyterian Hospital, the other a call for a mass meeting of the medical profession of the city of New York—the burden of the complaint being an alleged act of injustice done to certain medical gentlemen, through the failure of the Board of Managers to reappoint them on the medical staff of the hospital.

By the provisions of the Charter and Constitution of the Presbyterian Hospital, the property and concerns of the corporation are vested in and managed by a board of thirty-two managers. The Board of Managers has power to fill all vacancies, make by-laws, and appoint all such agents, assistants, and attendants as may be proper to carry out the purpose of such corporation. In pursuance of this power and authority, the Board of Managers adopted by laws for the government of the Board of Managers, and also rules and regulations for the government of the hospital.

By Section I. of the rules and regulations of the hospital, all physicians and surgeons connected with the hospital shall be appointed annually by the Board of Managers. The physicians and surgeons thus appointed annually constitute a Medical Board.

By Article VIII., Section 9, of the by-laws, if any officer, physician, or surgeon shall become unfit to execute the office, or misconduct himself . . . the visiting committee or any member of the Board of Managers may exhibit against him a complaint . . . and on notice to him . . . a majority of the managers . . . may discharge or remove the officer, physician, or surgeon complained of.

By Section II., Article 3, of the rules and regulations, the Medical Board at the regular meeting in May in each year shall elect a president, vice-president, and secretary. By Article III. of Section 2, the Medical Board has power to make rules for the internal management of the hospital, so far as the medical staff is concerned, subject to the approval of the Board of Managers; and Article VII. of Section 2 provides that in case of a vacancy in the Medical Board, they shall, *at the request of the Board of Managers*, recommend suitable persons for the appointment; but this article does not make it imperative on the Board of Managers to make this request.

All officers and appointees of the hospital know, or ought to inform themselves before taking office, of the by-laws, rules and regulations.

The general scope and meaning of the charter, constitution, by-laws and rules and regulations are evidently:

I. To vest the sole and exclusive power and authority in the Board of Managers; all appointees of whatever grade or description being subordinate to the Board of Managers.

II. To have the appointments of physicians made annually; and when such appointments are made, to have the term of office expire with the year; but for any misconduct which occurs before the expiration of the year, the offending person may be removed under Article VIII., Sec. 9 of the by-laws; and the appointment of any physician or surgeon does not give him a pre-emptive right to be reappointed. His re-appointment is a matter of discretion of the Board of Managers, as much so as his original appointment.

III. To vest in the Medical Board the power to elect its own officers; also to make its own rules, subject to the approval of the Board of Managers.

It must be apparent that the Board of Managers and the Medical Board should act in harmony, and co-operate with each other, otherwise the usefulness of the institution would be seriously impaired; and it is but fair to assume that the Board of Managers have the best interests of the institution in view, and are the proper parties to decide on all matters pertaining to the management of the institution.

And in view of the complaints made of these gentlemen, the question naturally arises, in cases of difference of opinion or of any disagreement, which power shall control, the principal or the subordinate? To remove an appointee before the expiration of the term of appointment must be considered a harsh measure. To fail to reappoint him, or, in other words, to drop him, is a fair, reasonable, and proper exercise of discretion in the appointing power, with which the appointee has no cause of complaint. It was intended that by the first section of the Rules and Regulations of the Hospital, the Board of Managers might keep such a control of the medical service that a person who was not disposed to co-operate harmoniously with the managers of the institution might—though not guilty of any such offence as is contemplated by Sec. VIII., Article 9, of the by-laws—fail of a reappointment, or, in other words, be dropped from the medical staff.

Referring to the two articles in question, the burden of their complaint seems to be that four members of the medical staff were unjustly punished for voting for the man of their choice for the position of president of the Medical Board.

Let us see if they have just ground for complaint.

It was well known to all the officers and appointees of the institution that Dr. White, the former president of the Medical Board, was a personal friend of Mr. Lenox, the president of the institution, and the one to whose liberality and bounty the hospital owes its existence; and it was also well known that Mr. Lenox, as well as the other members of the Board of Managers (with the exception perhaps of the "one medical gentleman" spoken of), earnestly wished and expected Dr. White to be continued in the position of president of the Medical Board.

Now, without reference to the capacity or superiority of Dr. White or his successor, one would naturally suppose that a decent regard for Mr. Lenox, as founder and patron of the hospital, and the man of all others whose wishes should be respected, would have induced the Medical Board, before dropping the man of Mr. Lenox's choice, to give some notice of their intentions and their reasons for dropping him, and then give *him* the chance (which they claim for themselves)

to resign, if he wished so to do, or to have a hearing (as they claim they should have had).

Did they do so? No. But with some others forming a clique, availed themselves of an accidental majority of *one*, at a slim meeting of the Medical Board, and, against the known wishes of Mr. Lenox and the Board of Managers, dropped Dr. White and elected one of their own clique, by the heavy majority of *one*; thus ignoring and snubbing Mr. Lenox and the Board of Managers. True, according to the strict letter of the Rules and Regulations, they had the formal right to do this; but had they the moral right? Was it in good taste, and conducive to harmonious co-operation hereafter with the Board of Managers, thus deliberately to put a slight upon Mr. Lenox? Was it right for these subordinates to arrogate to themselves a power contrary to the known wishes of the power that appointed them? Was it harmonious co-operation with the Board of Managers, for these gentlemen in the Medical Board to set up *their* choice against the known choice of the Managers? Was it not such an act of defiance and insult to the Board of Managers as to destroy their future usefulness?

The difference between these gentlemen "dropping" Dr. White as President of the Medical Board, and being themselves "dropped" by the Board of Managers, is simply this: These gentlemen and their clique endeavored to seize the control of the Medical Board, and to that end dropped Dr. White without cause or notice, and against the known wishes of Mr. Lenox and the other managers (with perhaps the exception of the aforesaid "one medical gentleman" referred to). The Board of Managers, in the exercise of a right given by the charter and by-laws, dropped *them*, by not reappointing them, because it was very evident that there would not be in the future any cordial or harmonious co-operation between them and the Board of Managers, and appointed four other gentlemen in whom they had confidence. In other words, the Board of Managers, not wishing to have anything further to do with these gentlemen, told them in a quiet way, by not reappointing them, that their services were no longer required. This they not only had a perfect legal and moral right to do, but it was a fair exercise of discretion. Furthermore, any publicity that has been or may be given to the affair is due exclusively to the fact that the four gentlemen dropped and their indiscreet friends are trying to make a mere private grief a matter of public notoriety.

These gentlemen and their clique had no scruples whatever in exercising what they claimed to be *their* right in dropping Dr. White without notice, thus fixing a precedent that could be applied to themselves; consequently, the Board of Managers had no scruples in dropping *them*, because the Board believed that the best interests of the Institution required it. "It's a poor rule that does not work both ways." These gentlemen set a precedent themselves, and gave a prescription to Dr. White that suited themselves; they surely ought not to make wry faces when their own medicine is given to *them*.

A few words in regard to the call for a mass meeting of the medical profession. This is simply ridiculous. What right has the medical profession to dictate to the managers of this or any other hospital who their appointees shall be? If the Board of Managers violate any law, they are amenable to the Law by a legal proceeding—not to a mass meeting. Suppose a trustee or vestryman of a religious corporation, or a director or a trustee of a bank, insurance company, or other corporation, should be quietly dropped by not being re-elected at a regular meeting, because his asso-

ciates or the power appointing him did not wish his company any longer; what would be thought of a call for a mass meeting of "outsiders" to take the matter into consideration?

To what good or evil would a mass meeting tend; and supposing it to have been held, what will have been accomplished?

NEW YORK, Nov. 27, 1875.

A CITIZEN.

OUR RELATIONS TO PHARMACEUTISTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Your excellent editorial on "Our Relations to Pharmacutists" deserves the careful attention of the profession, inasmuch as it involves the most vital points in medical reform. It is a crying outrage that physicians continue, despite "the ban of a reproach," to keep drug-stores in their own names, or to hold an interest in the same. This mixing of a profession with a trade is scandalous, and is an injustice to pharmacists, whose business is already too much overcrowded and cut up by competition. It is fair to presume that such Jacks-of-all-trades are masters of none, and it should be the duty of the medical profession to expel such men from its ranks, to "unfroek" them, and refuse them all social and professional intercourse while they are engaged in trade, or have any interest, by percentage or otherwise, therein. What is needed is more pride, more *esprit* in our vocation, and if medical men cannot make a living in the legitimate exercise of their calling, then in Heaven's name let them drop their degrees—at least have the good taste not to use their titles, nor be addressed by them, when for any reason they engage in business, or become medical boarding-house keepers, etc., etc. No measures should be considered too "unjust, unreasonable, or harsh" that would weed out such men, or force them to relinquish their titles, and take a regular course in pharmacy before examination for apothecaries or pharmacists.

As to the sale of nostrums by apothecaries, it is an evil not to be removed by law or regulations. It will rectify itself in time by the introduction of approved formulæ for all the purposes for which quack medicines are now vended. This plan has been suggested, and deserves the attention of the American Medical Association, who should appoint a committee to decide upon and approve formulæ which druggists could conscientiously recommend to their customers in place of these nostrums, and by the sale of which *as large a profit* could be made. The object should be to *displace* quack medicines by equally as good or even better remedies, so that the public may not be humbugged, and the apothecary convinced that he will be no loser by the change.

When our physicians are obliged to be well educated, academically and professionally, and examined and licensed by State Boards appointed by the Supreme Court and College of Physicians of each State; when they are prohibited from engaging in any trade, or having any interest therein, under penalty of expulsion and loss of their degrees; when our pharmacutists are regularly apprenticed and educated, and examined by disinterested State Boards, composed of apothecaries and physicians; when they are prohibited under a heavy penalty from prescribing over the counter, and from offering a "percentage" on prescriptions to physicians; when approved formulæ take the place of nostrums, and the public find more *tone* in all

the branches of medicine and pharmacy—then will come that "Millennium" for which we devoutly pray.
E. N. R. O. B. E. L. C.

PORTSMOUTH, N. H., Nov. 6, 1875.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Nov. 21st, 1875, to Nov. 27th, 1875:

LIPPINCOTT, H., Assistant Surgeon.—Granted leave of absence for one month. S. O. 90, Department of Arizona, Nov. 3, 1875.

NAVY.

November 27th.

WILSON, JOSEPH, Medical Director.—Ordered to special duty at Philadelphia in connection with the Centennial.

TONER, JOHN A., JR., Assistant Surgeon.—Ordered to the receiving ship *Wabash* at Boston.

HARVEY, H. P., Assistant Surgeon.—Ordered to the Naval Hospital at Philadelphia.

Medical Items and News.

THE PRESBYTERIAN HOSPITAL AFFAIR, AND HOSPITAL MANAGEMENT.—In answer to a call for a mass meeting of the medical profession, a large number of medical men assembled at the Union League Theatre on the evening of Nov. 30th. Dr. T. M. Markoe was elected chairman, and stated the object of the meeting, viz., the expression of opinion regarding the relations which should exist between the boards of management of our hospitals and their medical staff.

Dr. GEO. A. PETERS read a detailed statement of facts connected with the Presbyterian Hospital affair, with which our readers are already familiar; after which a committee appointed by the chair, consisting of Drs. Agnew, Thomson, Roosa, and Delafield, made the following report:—

Whereas, Certain facts have been laid before this meeting embodied in the following statements, viz., that,

At the Annual Meeting of the Board of Managers of the Presbyterian Hospital, for the year 1875, four members of the medical staff were not reappointed, and were thus virtually dismissed; that no charges were preferred against those gentlemen; that no causes were alleged to have existed which assumed fault on their part, nor was a hearing afforded them, although very respectfully asked for; that this is the more remarkable when we take into account the facts that the measures against the medical gentlemen not reappointed were carried by a single vote; that respectful protests from the medical staff and from a very large number of medical men were made to the board of managers, but not regarded; that the vacancies thus made were filled without consultation with the medical staff; that several members of the medical staff subsequently resigned; that a committee of the board of managers was appointed to confer with the gentlemen who had resigned; that the board of managers contemptuously refused even to accept the report made by this committee, although it was of a conciliatory character, and thus gave additional evidence of the

feeling that was entertained towards the medical profession.

That all the members of the committee except one, who was absent in Europe, instantly resigned. That other members of the board of managers, impressed by the injustice of these proceedings, also resigned.

In view of these facts, and of the principle that the good order and usefulness of hospitals must necessarily depend upon the maintenance of mutual respect and harmony between their boards of managers and their medical staffs, therefore be it resolved.

I. That the medical profession of New York cannot look with indifference upon these proceedings, but feel that such a precedent should not be established without protest on their part.

II. *Resolved*, That they believe that the four gentlemen dropped from the medical staff have not been treated with common justice.

III. *Resolved*, That no medical man should place himself in a position from which he may be dismissed without charges preferred or hearing allowed.

IV. *Resolved*, That we heartily approve of the action of those members of the medical staff who have resigned their positions, and thus refused to countenance an injustice done to fellow-members of their profession.

V. *Resolved*, That while we fully appreciate the great and wise beneficence of the founders and supporters of the Presbyterian Hospital in their efforts to secure a place of relief for the suffering poor, we deplore the treatment of the members of our profession, which has so much impaired the usefulness of what promised to be a great charity.

VI. *Resolved*, That in consideration of the primary importance of the relations of the medical profession to all hospitals, it is the sense of this meeting that similar occasions of disagreement between the boards of directors of hospitals and their medical staffs, as well as grave faults in the management or in the construction of hospitals, can be avoided only by an adequate representation of the medical profession in the membership of the boards of direction.

(Signed)

C. R. AGNEW,
W. H. THOMSON,
D. B. ST. JOHN ROOSA,
FRANCIS DELAFIELD.

Prof. T. G. THOMAS spoke to the resolutions at length, reviewing the recent action of the managers of the Presbyterian Hospital, showing the necessity of a harmony of action between the executive board and the medical staff. While admitting the right of the board of managers to elect its medical staff, he maintained that no member of the latter should be dismissed without cause.

He was succeeded by Prof. W. H. THOMSON, Prof. AGNEW, Prof. GILLETTE, Prof. ROOSA, Prof. JAMES R. WOOD, Drs. STURGIS, O'SULLIVAN, and QUIMBY, when the report of the committee was unanimously adopted, and the meeting adjourned.

THE EAST RIVER MEDICAL ASSOCIATION BANQUET.—The tenth anniversary of the East River Medical Association was celebrated on the 22d inst., by an enjoyable dinner at Sieghortner's restaurant, No. 32 Lafayette place, Dr. Robert A. Barry, the President of the Association, in the chair. Fifty members and guests were present, and after dinner had been discussed, several ladies, the wives and daughters of the members, were introduced and were present during the remainder of the programme. The President felicitously prefaced the toasts of the evening by a brief historical address, in which he reviewed the progress of the Society from the date of its organization.

DR. VERRANUS MORSE eloquently responded to the toast, "Our tenth anniversary: in the day of prosperity be joyful." This was followed by the sentiment, "Our departed ones,—gone, but not forgotten," standing, and in silence. After which a dirge by the band.

The Rev. WM. N. DUNNELL, Rector of All Saints', spoke to the following: "The Clergy, our coadjutors: to them is committed the cure of souls, as to us is delegated the cure of the body. Together may we so entwine the healing art as to realize the promise of the life that now is and of that which is to come."

MR. CLARK BELL, of the New York Bar, ex-President of the Medico-Legal Society, followed in response to the toast, "The Bar, our ambitious rival: while the doctor is satisfied if he can keep his patients in a condition to will and do for themselves, the lawyer aspires to make their wills and deeds for them."

"Our Medical Schools: not unmindful of our early training, and true to our alma maters, we greet to-night their present official representatives."

Chancellor HOWARD CROSBY responded for the University Medical College, in his happiest vein. Dr. Chas. S. Roberts followed for the College of Physicians and Surgeons in the absence of Prof. T. Galliard Thomas, who, in consequence of a recent family bereavement, had sent his regrets; while Dr. James W. Bowden took up the gauntlet for the Bellevue Hospital Medical College, and paid a glowing tribute to his preceptor, Prof. James R. Wood, the expected respondent.

"Our Sister Societies—the Academy and the County—though old maids, their families are large and respectable," being next in order, the President, after reading a letter from Dr. Saml. S. Purple, the President of the former, and announcing the unavoidable absence of Prof. H. B. Sands, the President of the latter, called upon Dr. Horace T. Hanks, as one of the Vice-Presidents of "the County Medical."

"The Medical Press—Adjunct Professorships and Post-Graduate Course of Instruction," was responded to by Dr. John Shradly, followed by Dr. John P. Garbish.

"The Daily Press: the magnetic wire that puts us in communication with all the ends of the earth," brought up Mr. Isaac Henderson, Jr., of the *N. Y. Evening Post*, who discoursed upon ideal journalism.

DR. TRUMAN NICHOLS responded for "Woman—the physician's best friend," in a characteristic speech, abounding in humor, poetry and philosophy.

The President in the course of the evening announced the death of the Hon. Henry Wilson, Vice-President of the United States, and called upon Frederic Wagner, Esq., as a friend of the deceased, to respond.

DR. WILLIAM NEWMAN, in behalf of his colleagues upon the Anniversary Committee, Drs. John Burke, George V. Skiff, Verranus Morse and Truman Nichols, replied to the vote of thanks unanimously passed in recognition of their efforts to make the occasion a success.

Original Communications.

CASES OF BENIGN AND MALIGNANT TUMORS TREATED BY ELECTROLYSIS.

By GEORGE M. BEARD, M.D.,

NEW YORK.

IN a recent communication to the RECORD I stated in general what could and what could not be done in the treatment of tumors by electricity. In this paper I will illustrate by a few cases some of the propositions then advocated.

Some of the cases, it will be observed, differ in the methods and combinations of methods used, from others previously reported; while others but confirm the results of experiments already made public.

CASE I.—A Glandular tumor disappears under persevering treatment by external galvanization and faradization, and electrolysis.

Mr. J. C., aged 23, was referred to me, May 2, 1874, by Dr. Mitchell, for a glandular tumor on the left side of the neck below the ear. Six months the tumor had existed, and it had resisted iodine internally, and other methods also. For a number of times I used external galvanization, and sometimes faradization with strong interrupted currents, with a view to break up the tumor by the mechanical action of the current, as suggested by Meyer.

These methods did not have the effect to reduce the size of the tumor, but caused it to soften in the centre, and on the 26th of May I opened it. Considerable pus and blood escaped, and I then treated the cavity by mild electrolysis with a needle connected with the negative pole. This treatment was used a few times, and the tumor subsided and the wound healed. Glandular tumors as a rule do not yield rapidly or brilliantly to the electrical influence, whatever the method of application. In the above case there was nothing of the immediate rapid subsidence that we sometimes see in goitres after one or two applications; but the end was attained by constant hammering until softening occurred, and the process of absorption after the evacuation of the pus appeared to be aided by the electrolytic treatment.

I have seen glandular tumors and enlargements resist utterly external faradization and galvanization, and even when the needles are used the tumor will not always soften as in the above case.

CASE II.—Ganglion treated by electrolysis.

A lad, aged 14, referred to me by Dr. Bennett, had a weeping sinew on the wrist. It had reached the size of a large walnut. The patient was fully anaesthetized, and two needles, one connected with each pole, were inserted into the tumor, the positive needle being kept *in situ*, and the negative worked in various directions inside, so as to electrolyze all the internal surface. The operation lasted ten minutes. A small amount of decomposed fluid escaped at the hole made by the negative needle, and the swelling subsided, perhaps about one-third or one-half.

The tumor was dressed with a pad, over which a bandage was tightly drawn. For two or three days there was some inflammation and considerable pain, but in a few days the inflammatory signs disappeared, and the tumor appeared only as a flattened elevation. The result was, therefore, most satisfactory. It may

be noticed that the method of electrolysis used in this case was similar to that which I have employed and recommended for cystic growths in general; in fact, this weeping sinew was treated precisely as any cystic tumor, which is the very reverse of the method of working up the base that I use for malignant growths. In cystics of a benign character, when the walls are moderately firm, I *work up the inner or secreting surface* by passing the needle into the body of the tumor, and press the point in all directions against the inner surface. By this method a threefold object is accomplished: the evacuation of the fluid constituents, which of itself alone is of slight moment, and would not avail to cause absorption of the tumor; the artificial inflammation of the inner surface, so that secretion is stopped; and finally the general absorbent effect of electricity upon the inner surface and upon the body of the tumor.

The inflammation excited by electrolysis appears less inclined to extend than inflammation excited by most other causes. I form this opinion from clinical observation simply.* In the above case I should have been apprehensive lest the inflammation would extend up the tendon, and perhaps cause annoyance, were it not for this fact, that inflammation excited by electrolytic action is usually circumscribed, however severe it may be.

Hydrocele, if treated by electrolysis, should be treated by this method, and some of the failures and uncertainties attending electrolysis in hydrocele can, I suspect, be explained by the fact, that the treatment has been used with a view only to decompose and evacuate the contents of the sac, while the secreting surface has not been touched. It is true, I admit, that in some cases the irritation caused by introducing the needle, and the action that takes place near it when by chance it may strike the inner secreting surface, may be sufficient to bring about a permanent cure. In one such case of hydrocele in a child, where the little patient would not bear thorough treatment, a single introduction of one needle, and the application of a mild current for a short time by Dr. Sterling, was enough to cause permanent disappearance of the hydrocele, but such results are exceptional, and are not to be expected.

CASE III.—Nævus of the cheek—Disappearance after two electrolytic operations.

A child five months old had a nævus on the middle of the left cheek. The growth appeared to be a combination of the external and cutaneous, being somewhat raised above the skin and extending downwards so as to involve the skin, and making it necessary for the operation to be very thorough; and on examining the tumor I felt assured that ordinary mild electrolysis with a feeble current would do little or no good—that a thorough operation should be used, or none at all; and it seemed best to try a method resembling that employed in working up the base of malignant tumors. I was confirmed in this decision by the fact that the case had been operated on by mild electrolysis very many times, and no good had resulted, and the tumor was about one inch in length and three-quarters of an inch in breadth, and was increasing in size; its first appearance being when the child was a few days old.

May 24th, I operated twelve minutes with ten weak cells; a needle connected with each pole being inserted at the base, the positive being kept *in situ*, and the

* In the case of a large subcutaneous erectile tumor on the head of a child, on which I twice operated for Dr. Alfred C. Post, at the Presbyterian Hospital, serious symptoms occurred, although the tumor was solidified and absorbed, and the patient recovered.

negative worked in various directions until two-thirds of the tumor was destroyed.

May 31st, I again operated with twelve cells for ten minutes in the same way, and completed the dissolution of the tumor from the base through the borders in all directions where enlarged capillaries appeared.

In both operations an anæsthetic was used. The method of electrolysis used in this case was a sort of compromise between the full method of electrolysis of the base used for epithelioma, and the method generally employed for nævi. The needles were not inserted any considerable distance from the body of the tumor, and not at all into the healthy tissue, but only into those parts where the vessels were enlarged.

After an operation of this kind there must be a scar: this was expected, and any attempt to treat a case of that peculiar kind by electrolysis, or by any other method, without leaving a scar, would fail.

May 11th, 1875, the scar was about an inch long, and was almost colorless.

CASE IV.—*External nævus treated by electrolysis—One operation—Successful result.*

A child two years of age was seen by me with Dr. Bird, April 11th, 1874. On the left cheek there was an external nævus, about the size of a filbert. It presented no unusual appearance, and as some very mild tentative operations had failed, it was thought best to use a sufficiently strong application to do the work at once. The parents were fearful of an anæsthetic, the father preferring to hold the child during the operation, which was performed with a moderate current from a few cells, and lasted about fifteen minutes; with an anæsthetic a stronger current could have been used, and the application would have been shorter. A single needle attached to the positive pole was inserted into the nævus, and the circuit was completed through a sponge at the negative pole held near by. On account of the struggling of the child the operation was carried out at great disadvantage, especially as the desire was to make as little disfigurement as possible. In regard to the best method of electrolysis for "port-wine stains," I am not decided. Two or three cases of that kind are now under my observation. Dr. Althaus, of London, in a paper recently sent me, says that five or six operations are sometimes necessary for these cases; and implies that in this way they may sometimes be removed without disfigurement.

I may say here, that it is of immense advantage, in most of these operations, to have the patient fully anæsthetized; and as young children almost always, I believe, bear ether or chloroform well, even mild and short operations are better performed when these agents are freely used. The moving and displacement of the needles by the motions of the suffering patient, cause the disfigurement to be greater than it would be otherwise, as well as make the task of the operator much harder. Local anæsthesia will hardly answer for many of these cases, and the hope expressed by Dr. Althaus,* that croton chloral would answer the purpose for benumbing the nerves of the face, has not, according to my observations, been fulfilled.

It is worthy of remark, that young children bear electricity, faradic and galvanic, better than adults. They feel the temporary pain caused by the chemical or mechanical action of the current on the body, just as they would feel any other irritation; but the unpleasant secondary or reactive effects sometimes seen in adults after severe or prolonged applications, they do not appear to experience. This remark applies, not

only to applications on the body in general, but to applications, electrolytic or external, around the head, neck, and face. I insist on this fact, which has been made evident to me by special and systematic experiments in the treatment of young children, because on the part of some there is apprehension lest evil effects may follow electrolytic operations on infants but a few weeks or months old. On *a priori* grounds it would be supposed that children would be more susceptible to the electrical force than adults; our general knowledge of the impressibility of the nervous system in early years would make this supposition quite probable; but in this, as in so many matters, reasonings based on our necessarily imperfect physiological knowledge must yield to the conclusions of experience.

CASE V.—In a case of hemorrhage from the gums, the effects of mild electrolysis were very interesting. For two years a lady of middle life, a distinguished actress, had been annoyed by repeated and oft-recurring hemorrhages from the gums of the upper jaw. The blood came from the gums just behind the middle incisor teeth, and it was impossible to tell its precise point of exit. There was no swelling, no ulceration, no inflammation or congestion, at ordinary times; indeed, there was nothing to distinguish that portion of the gum from any other portion, or from the gum of a person in health. At times, there would be a fullness, a filling up, so to speak, of that portion of the gum, and the blood would flow freely. This accident would occur at any time of the day, but quite regularly in the morning. One time she was taken while acting before an audience. The amount of blood lost at each hemorrhage was considerable, varying between half an ounce to a wine-glassful, but the local remedies that had been tried, including of course the persulphate of iron, made no permanent impression. The patient was generally debilitated and was suffering from hepatic disorder, and her debility was increased by the frequent losses of blood.

I decided to use electrolysis, although I knew not just where to put the needles; but hoped that the coagulating effect of both poles on the capillaries of the gums might have a tendency to diminish, if not to stop, these hemorrhages.

Being a lady of very great power of will, and somewhat fearing ether, the operation was performed without an anæsthetic. A small needle, connected with the positive pole, was inserted about one-eighth of an inch into the gum just between the incisor teeth, and another small needle, connected with the negative pole, was inserted the same distance into the gum near by. A very mild current was used, for this part is sensitive to electricity as to every other form of irritation. The operation lasted but seven minutes, and was twice interrupted on account of the pain produced.

For a week after this operation there was no hemorrhage; electrolysis had thus accomplished more than any treatment that had been used.

March 12.—The operation was repeated with a somewhat stronger current and longer application.

In a few weeks the patient died from, as it was reported, disease of the liver.

Malignant tumors, if large and hard, may be removed with the knife, and the base thoroughly electrolyzed in all directions; but if they are small they can be removed by the electrolysis, and the base may be electrolyzed at the same time: the same operation that removes the tumor also works up the surrounding tissue.

The healing is rapid and very satisfactory after ope-

* Archives of Electrology and Neurology, Vol. 1, No. 1, p. 1, 1874.

rations of this kind, even when the wound is quite extensive and much sloughing takes place; and on *a priori* grounds it would seem that there would be less likelihood of a return than when the divided parts are closed to heal by first intention. Some of the cases on which I have operated by this method during the past four years I see occasionally, and are doing well; others I have lost sight of entirely. In one of the following cases there was, in less than a year, a return of the tumor, but, as will be seen, the case was one far advanced. Some cases that I have seen have been so far gone, the cancerous cachexia so marked, that all I have tried to do was to relieve the pain, and make the patient more comfortable.

CASE VI.—*Scirrhus of the breast—Removal by the knife—Electrolysis of the base.*

In the summer of 1875 I used the method of electrolysis of the base in a case of scirrhous of the breast, under charge of Dr. Stephen Smith, at Bellevue Hospital, who first removed the tumor and an enlarged gland in the axilla by the ordinary method, and left the wound open.

In operating I used the long cutting needles connected with both poles, and a current of considerable strength. The whole base was electrolyzed more or less with one pole, and some of the time the narrow electrode was used.

The patient did well after the operation, but was attacked with erysipelas—so I was informed by Dr. Smith—which travelled in various directions over the body. There was, I believe, some erysipelas in the hospital at the time. The healing went on most satisfactorily even during the attack of erysipelas. She left the hospital when she was able to do so, and we lost sight of her.

CASE VII.—*Epithelioma of the face treated by electrolysis of the base.*

An old man, who represented himself to be between 70 and 80 years old, appeared at the Department of Electro-Therapeutics and Nervous Diseases, Denilt Dispensary, in the spring of 1874, with a long, narrow ulcer—clearly an epithelioma—on the left side of the face below the eye. It was about half an inch in width, and extending from the zygomatic arch half-way up the nose. The bone was apparently nowhere affected, and hence it was believed that the case would be a favorable one for the method of electrolyzing the base in spite of the age of the patient.

The patient was fully etherized, and, in the presence of a number of medical men, the long cutting needles were inserted beneath the growth in various directions, and the whole base and the surrounding tissue for some distance thoroughly worked up. All portions of the growth fell off during the operation, so that there was no occasion for the use of the knife. The patient came out of the operation—which was about half an hour in length—very well, and walked home. We have not been able to keep track of him.

CASE VIII.—*Large epithelioma of face treated by excision and electrolysis of base—Recurrence.*

Mr. G. F. O., aged 70, strong and vigorous, was referred to me Jan. 8, 1874, by Dr. J. H. Wikoff, of Princeton, N. J. Two years before, the patient cut himself with a razor on the right side of the face, over the malar bone, while shaving. The scratch was a slight one; but it did not heal, and in the course of a few months it became quite hard, and this hard tissue assumed in time the appearance of an epithelioma. Dr. Wikoff first operated on the tumor July 5 by liga-

ture; Sept. 13 used caustic potash, and Dec. 12 operated by subcutaneous ligature. After all these operations the tumor quickly returned. At the time when I first saw it, it was about the size of an English walnut, ulcerated in the centre, with a hard base.

It was decided to operate by the method of working up the base, combining with it the knife to shorten the operation. On Tuesday, Jan. 13, I operated, with the co-operation of Dr. A. B. Crosby; Dr. J. Van Bibber assisting, and Dr. N. B. Emerson giving the anæsthetic.

Dr. Crosby first made an incision through the skin, around the tumor, in the healthy tissue. A wire connected with the galvano-cautery battery of the Galvano-Faradic Mfg. Co., heated to white heat, was applied in the incision and allowed to remain there until the hemorrhage stopped. The application of the cautery was not necessary, but was used as a convenience merely in checking the hemorrhage. The use of the knife was not absolutely necessary, but much shortened the operation, since it saved all the time that would have been required in working through the skin with the needles.

I next plunged one of my long cutting needles beneath the tumor, and connected it with the positive pole of a zinc-carbon battery; the negative needle, which was narrower, thinner and sharper than the other, I placed also beneath the tumor, into the base, through the line of the incision, and at a little distance from the positive needle. The current was gradually increased to twenty cells, when the electrolytic action was very powerful, and the negative pole soon began to be loosened; and I slowly worked it sidewise, until in about fifteen minutes the tumor was dislodged and was taken off. The base was then carefully and thoroughly worked up in all directions until all the hard tissues had been destroyed, and the cavity presented a charred appearance. The entire operation lasted nearly an hour. A small arterial branch was ruptured, which was tied by Dr. Crosby. The patient came out of the ether well, and returned home the same afternoon. To my great astonishment he had no irritative fever on the following day, but was able to go about. Much less sloughing than usual followed, and very soon the process of healing began. The complete healing was not accomplished, for up to the middle of March a small scab remained. The wound was dressed by the suggestion of Dr. Crosby, with oakum and carbolized oil.

The tumor was taken for microscopic examination to Dr. Francis Delafield, who gave the following report:

JANUARY 20, 1874.

"The specimen received from you consists of an ovoid piece of skin, in which is a deep ulcer. The walls of this ulcer are formed of granulation tissue, in which are imbedded nests of epidermis cells closely packed. The surrounding skin is infiltrated with groups of small rounded cells, with a few similar nests. This infiltration extends through nearly all the skin removed.

It is probable, therefore, that the removal was not a complete one, but that some portions of the new growth were left behind.

The growth has the usual appearance of epithelial cancer of the face."

The tumor recurred, and I again operated in the same way, although not sanguine of the results, but hoped at least to keep the disease at bay. The operation was more thorough than the first, the needles extending as far as it was safe to do without injuring the temporal artery. It was clear that the disease had attacked the bone, and that however radical might be

the removal of the soft parts, and however thorough the electrolysis, there would be a probability of recurrence in time. I learn that the tumor did recur, or rather that the healing was not complete.

Out of a large number of malignant tumors on which I have operated by this method, in four only did the wound refuse to heal, and in two of these the healing, up to a certain point, was, in the estimation of the surgeons who saw them, surprisingly good.* This is one case of epithelioma of the face in which the operation did not work well. It would be very desirable, if it were possible, to make a fair and full comparison of this method of electrolysis of the base with the ordinary method of operating with the knife, or with the treatment of the base by caustics. Such a comparison, to be of value, must include quite a number of cases, studied by experienced surgeons and operated in all the methods, and these cases should be watched for months and years after the operation. An extended comparison of this kind is perhaps impracticable, and in lieu of it we can only judge by careful study of all cases on which this method is used, and keeping them under observation as long as possible. Points already proved are, that the healing after this method is very satisfactory, that pyæmia does not follow, that the irritative fever, when it occurs, is not dangerous, and that in a certain proportion of the cases the results are permanent, and apparently more so than after simple excision. My friend Dr. W. F. Hutchinson, of Providence, has had much experience with the method of electrolysis of the base, and reports very favorably of it.

CELLARS AND DIPHThERIA :

TOPOGRAPHICAL OBSERVATIONS OF TWENTY RESIDENCE SITES, IMPARTIALLY SELECTED, IN WHICH DIPHThERIA HAS OCCURRED, IN THE CITY OF DES MOINES, DURING THE SUMMER OF 1875.

By A. G. FIELD, M.D.,

DES MOINES, IOWA.

In nine residences, with thirty-eight inmates, an alluvium overlying sand and gravel, with dry cellars beneath, and insufficient side ventilation, there were twenty two cases and four deaths.

In two residences, with fourteen inmates, on alluvium overlying sand and gravel, with wet cellars and insufficient side ventilation, there were four cases, but no deaths.

Five residences, with twenty-six inmates, on alluvium, clay subsoil, damp cellars, with insufficient side ventilation, there were fourteen cases, and three deaths.

Two residences, with fourteen inmates, on filled ground over alluvium, clay subsoil, wet cellars, with insufficient side ventilation, there were nine cases, and four deaths.

Two residences, ten inmates, on low ground, damp cellar, in alluvium with insufficient side ventilation, there were four cases; no deaths.

A window, or an outside door on the south or west only, from which directions come the prevailing winds, as well as openings through basement walls less in the aggregate than one square inch for one square foot of area, are deemed insufficient for ventilation; and more especially so where a door opening through the floor into the cellar has been in daily use. In four instances there was no outside opening whatever. These

observations were made, not with a view to sustaining some preconceived opinion or favorite theory, but to arrive at, as far as possible, some of the peculiar conditions under which diphtheria has originated.

The classified grouping shows a cellar or ground excavation under all of the residences where the disease has occurred, and that the greatest fatality has been where the natural surface, previously buried beneath filled earth, has been excavated, thus exposing a zone of great porosity between the original surface and filled earth. The fair inference would be, that with the natural surface was buried also more or less of organic matter, the volatile products of the decomposition of which would thus find an easy outlet; and, therefore, there has been the greatest fatality where the circumstances have been most favorable for the escape of the largest amount of ground air. The lines of greatest porosity in the earth's substance lie more or less parallel to the surface, favoring lateral currents, and this fact applies more especially to these drift formations; and wells, cellars, and shafts afford the most easy escape for ground air, containing as it does a large per cent. of carbon, nitrogen, and other products of the decomposition of organic substances. But that ground air does escape through the more compact surface when no excavation offers, is beyond question; and it is only necessary that a dwelling be exposed to the confined air beneath it, to subject its inmates to the deleterious consequences of such poison, if it is not the pabulum and natural habitat also of noxious living organisms.

Another condition presented in the grouping is moisture. It is not certain that a dry cellar in so porous stratum as sand and gravel is, gives forth less water vapor than one in clay containing water does, although the latter certainly affords less ground air, and it is pretty safe to assume that in cellar air in general is an excess of water vapor. This of itself, within a certain limit, is not harmful, and some virtue even is attributed to it as employed in the celebrated *Spas* of Europe, and by residence upon the sea-shore. But the air of the sea-breeze, triturated in adverse currents, and even that of the prairie winds with often traces of ozone also, is comparatively free from organic impurities. That a moist atmosphere in the ordinary course of natural events may so modify or develop the elements of organic matter as to become accessory to, or productive of, zymotic poisoning, three conditions of it are essential: 1st. A temperature above 50° F. 2d. A state of comparative quiescence or stagnation. 3d. The presence of the products of organic decomposition. All of these conditions are present in a very large majority of unventilated cellars, as well as beneath houses without cellars, where atmospheric air does not have free access.

Here another fact that has happened to come under observation may justify a digression. For the year ending Sept. 1st, 1875, seventy-three (73) per cent. of the interments in potter's field, as is shown by the register of the sexton, were of children five years of age and under (who were, consequently, mostly confined to house air); while in the cemetery proper only fifty per cent. of those interred during the same time were five years old and under. And in potter's field the average age of those buried during the same period is ten + years, while in the cemetery proper it is twenty + years. When these facts are associated with the further facts, that seven-eighths of those whose dead are buried in potter's field live upon the low grounds or sandy flats that constitute the point above the confluence of the Des Moines and Raccoon Rivers, and extend also east of the former and south of the latter;

* One of these cases—a scirrhus of the rectum—was reported by Dr. Crosby in the Archives of Electrology and Neurology, Vol., No. 1.

while a large majority of the better-to-do citizens reside upon the higher bluffs that on every hand surround the business portion of the city, they have an unmistakable significance. In these sandy flats that are the older portion of the city stables, cellars, privy vaults and wells have, for many years, been interspersed with nothing that approximates or deserves the name of sewer to mitigate the consequences.

But to return to the subject proper of this paper; the following deductions may be drawn from the observations:

That all ground exposures of cellars should be cemented. Floors over them should be tight, and inside doors never allowed.

That cellars constructed with a fire-place in them, with an adequate chimney extending to the top of the building, to be used for ventilation, may remove to a large extent the evils arising from sub-dwelling basements and cellars.

That in all instances where such ventilation is not provided side openings in all of the cellar walls should be in constant use, such openings to be not less on each side than one square inch for every square foot of corresponding side and area.

Progress of Medical Science.

STRICTURE OF THE URETHRA IN THE FEMALE.—Dr. Robert Newman reports four cases, which are presented as examples of true stricture of the female urethra. They were all met with in the course of eighteen months. It is thence inferred that urethral stricture is not such a rare occurrence in women, as the slight mention accorded to the subject in the literature would lead one to suppose. A constriction was detected in each case by means of bougies, varying in size from No. 1 to No. 8. They occupied various portions of the canal: at the meatus at three-quarters of an inch, and seven-eighths of an inch distance from the meatus; and in one case, it is said, involved almost the entire urethra. As for the causes of the strictures, one case was attributed to syphilis, one to irritating injections in gonorrhœa, one to granular urethritis, and one to general urethritis occupying the whole length of the canal. The principal agent employed in the treatment of these cases was electrolysis, and in each instance it proved entirely successful. The method of its application consisted in the patient's holding the sponge electrode of the positive pole in the palm of the hand, while a metallic bougie, varying in size according to the amount of constriction, was connected with the negative pole of the battery and passed down to the stricture. In a few moments the latter readily yielded to the galvanic action, and a larger instrument could be introduced. Three or four sittings, at intervals of from a few days to a week or more, sufficed to effect a cure. From five to eleven cells of Drescher's battery were used, and the strength of the current was always gradually increased from zero until a feeling of warmth and a slight prickling sensation were produced. In the fourth case, which seemed to be owing to a previous blennorrhœa, the meatus urethræ would only admit a sound smaller than No. 1 of the English scale. A No. 6 metallic olive-shaped bougie was pressed against the meatus, and eleven cells of the battery were employed for five minutes. The instrument advanced for half an inch,

when "a fibrous band was distinctly felt stretching across the urethra. This was overcome by degrees, and another stricture was discovered just anterior to the bladder." Two days after the operation, a "carneous plug" was discharged from the urethra, and the patient was greatly relieved. After two more applications she was discharged as cured.

Allusion is made to a "spasmodic stricture" in a fourth case, which was likewise treated successfully by galvanism. It is not stated that spasm had anything to do with either of the other cases.—*The American Journal of the Medical Sciences*, October, 1875.

CAPILLARY PUNCTURE OF THE INTESTINES IN TYMPANITES.—An interesting article in the *Bulletin Médical du Nord*, by Dr. Cuignet, contains the following points:

1. The puncture should be made by giving a rotary motion to the needle, which is held between the fingers at the surface of the body.

2. It can be perceived the moment the needle reaches the gaseous cavity as well as the moment it touches the opposite wall, thus showing the exact dimensions of the cavity.

3. The gas does not escape spontaneously, however distended the cavity may be which contains it, but it must be withdrawn by aspiration.

4. Only the fold of intestine in the immediate vicinity of the puncture must be evacuated, but all of the folds of the intestine must be punctured to obtain any considerable relaxation.

5. Each fold as it is punctured collapses, and its place is filled by the two folds above and below it, which maintain the tympanites in the same region, until they also are punctured.

6. Either the gas alone may be withdrawn, or both the gas and the liquid matter in the intestine, by graduating the depths to which the needle is made to penetrate.

7. It is esteemed prudent to always extract the liquid in the vicinity of the puncture.—*La Tribune Médicale*, October 3, 1875.

THE PRESENCE OF DEXTRINE IN THE URINE.—It is stated that under the influence of the alkaline waters (Vichy, Vals, Carlsbad) the sugar entirely disappears from the urine of diabetic patients, but that the liquid still continues to act feebly as a reducing agent in Fehling's test. According to E. Reichardt, of Jena, this is owing to the presence of a small quantity of dextrine. His method of analysis is as follows: The urine is evaporated over a sand-bath to a syrupy consistence; the residue is treated with alcohol and caustic potash as in testing for sugar; a deposit is formed, from which the supernatant liquid is easily separated. The deposit is washed several times with absolute alcohol, and then treated with dilute acetic acid, by which it is dissolved. The addition of absolute alcohol again reprecipitates the dextrine; the alkaline acetate and the sugar (of which slight traces exist), remain in solution. After being well washed with alcohol, and then dried, the precipitate becomes a white powder of an insipid taste, and soluble in water; its aqueous solution reacts very slowly to Trommer's test, very dilute sulphuric acid transforms it into glucose, which reacts to Trommer's test immediately. On contact with iodine the powder becomes of a brownish-red color. The elementary analysis gives the $C^{34} H^{20} O^{20}$ of dextrine or glycogene. Nothing is said with regard to its action on polarized light.—*Journal de Pharmacie et de Chimie*.—*Journal de Médecine*, Aug., 1875.

NON-REGENERATION OF THE CRYSTALLINE LENS IN MAN AND IN THE RABBIT.—M. J. Gayat stated recently before the French Academy of Sciences, that there was no well authenticated case on record where the lens in the human subject had been regenerated. Moreover, experiments upon rabbits had led him to the conclusion, contrary to the opinion maintained by others, that the lens in these animals also is not regenerated. The results of his researches are expressed as follows:

1. In young rabbits, when the interior of the capsule has been carefully laid open, and almost the entire lens has been removed, after several weeks certain more or less transparent masses are observed, which have some of the histological characters of the normal crystalline lens.

2. In older rabbits these productions are less constant, and differ from the normal lens still more in their anatomical characters.

3. The intracapsular masses, heretofore regarded as new formations, are merely the consequence of the normal development of the crystalline elements which remain adherent to the capsule, even after the most thorough extraction of the lens.

4. The crystalline mass observed is the more considerable the greater the interval between the extraction and the autopsy of the eye, and the younger the animal, that is, the farther it is from its period of complete development.

5. The sum of the masses extracted and of those found in the eye at the autopsy approximate nearly in weight to that of the other eye left intact.

6. There is no reproduction, or scarcely any, in the neighborhood of the lacerated lips of the capsular wound.—*Gazette Médicale de Paris*, Sept. 25, 1875.

THE FORMATION OF URINARY CALCULI.—Utzmann has been studying the origin and development of calculi by the aid of carefully made sections of a large number of specimens. He found that in 480 calculi of primary, *i.e.* renal origin, the nucleus in 441, *i.e.* 91.8%, was uric acid; in 31, or 6.4%, oxalate of lime; in 8, or 1.6%, cystine. With regard to their composition, he finds that among 224 vesical uric acid calculi the nuclei in 208, or 92.8%, were uric acid, in 15 oxalate of lime, in one, earthy phosphates; among 130 oxalate vesical calculi, 124 nuclei were uric acid or 95.4%, five were oxalate of lime, one was earthy phosphates; among 185 phosphatic vesical calculi, 109 nuclei, or 58.9%, were uric acid, eleven were oxalate of lime, two were cystine, eighteen were foreign bodies, and among six vesical calculi of cystine the nuclei were all of the same substance; among multiple calculi, out of four cases aggregating seventy-three stones the nuclei were all of uric acid. With regard to renal calculi spontaneously discharged, out of a total of 319 he found a nucleus of uric acid in 306, or 99%; of oxalate of lime in four, of cystine in nine. Of nine large renal calculi the nucleus was uric acid in seven, or 77.7%. Also it was of uric acid in all of five urethral calculi. Thus in the whole number uric acid forms the origin of the calculus in 93.8% of primary calculi. In infants too his investigations agree with those of Civiale, that uric acid concretions are very influential in the formation of calculi. Moreover concretions of oxalate of lime were never found in the new-born child. After reviewing the opinions of other authors on the primary formation of calculi, U. expresses his own conviction that the primary formation is always in the kidneys from urinary deposits, *viz.*, uric acid, urate of soda, oxalate of lime and cystine; while the secondary formations are as constantly in the bladder from deposits from alkaline urine, such as urate of ammonia, carbonate of lime, amorphous phosphates, ammonio-

magnesian phosphate and crystalline phosphate of lime. The greater the acidity of the urine, too, the greater the tendency to the formation of calculi, owing to the shape and character of the uric acid crystals there deposited. Food, drinking-water, constitution, etc., also exert their influence.—*Wiener Klinik*, May, 1875.—*Rundschau*, Sept. 15, 1875.

THE PUERPERAL DISEASES OF THE MAMMÆ.—At the lying-in institution at Dresden, Dr. Huebner has collected some statistics of the most common affections of the breasts in puerperal women. He finds that of 2,300 women who were able to nurse, 918 or 39.9 per cent. suffered from affections of the breast. It is supposed that the results of similar observation in private practice would be more favorable than those made in a hospital. 40 per cent. of those attacked were primipare, and the thirty-third year seemed the most liable to such difficulties. The conditions favoring those diseases were a strong constitution, a delicate skin, a medium or small size of the breast, a short and retracted nipple—one difficult for the child to get hold of—a bad development of the parenchyma of the gland, and a small quantity of secretion in the gland previous to confinement, as against the opposite state of these facts. The pressure and suction necessarily exercised by the child in the act of nursing determine, as primary affections in the nipple, redness, erythema, vesicles, and fissures, followed secondarily by swelling of the nipple, of the milk ducts, with scabs, erosion, and ulceration. Eczema is to be considered as a special disease. In addition to these affections the areola is liable to follicular abscess and partial inflammations, resulting in localized indurations. Inflammation of the parenchyma of the gland, or mastitis parenchymatosa proper, appears to begin as a hyperemia of the interacinous tissue, with exudation into the meshes of the connective tissue, leading to strangulation and inflammation of the separate acini, the pain being due to pressure on the nerves. These changes are accompanied by increase of temperature and of the frequency of the pulse. Wounds of the nipple, blows on the breast, a chill or a powerful mental emotion, may, on the second, third, or fourth day, convert the physiological swelling of the gland into a mastitis. Among 2,300 nursing puerperal women, the author found 136 cases of mastitis. He states that a previous mastitis does not prevent nursing subsequently, nor does nursing often evoke a new mastitis, although marked alterations in the gland and many cicatrices and contractions predispose to it. His treatment of all lesions of the nipple and areola consists in the constant application, day and night, of lukewarm compresses, wet with lead-water; fissures, ulcers, and excoriations being touched once or twice a day with balsam of Peru, and the breast well supported. The child should nurse less often than usual, and where possible through a nipple shield. He recommends the warm lead-water in mastitis also, to be followed by strapping of the breast and free incision, while suppuration is promoted by poulticing.—*Deutsche Ztschr. f. prakt. Med.*, 21 and 22, 1875; *Schmidt's Jahrb.*, Sept. 8, 1875.

NEW SOURCE OF LEAD POISONING.—M. Lancereaux has discovered a source of saturnine intoxication in the yellow cord-fuses used for lighting cigars. The yellow color is produced by the chromate of lead in a workshop where the fuses were manufactured. L. has found that all the workmen had the lead border upon the gums. One of them, whose duty it was to reel the thread, and who absorbed more of the yellow dust than the rest, suffered from lead colic.—*Lyon Medical*, Oct. 3, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

New York, December 11, 1875.

PRESCRIBING APOTHECARIES.

THERE is perhaps no question connected with the mutual dependence of physician and apothecary which calls for a more thorough discussion than that of shop prescribing by the latter. We are well aware that many of the leading pharmacists are ready to deny that the practice is prevalent, but that they are mistaken in such an estimate every physician who has had anything to do with the ordinary run of apothecaries knows to his sorrow. A physician can hardly enter a drug-shop without hearing the proprietor addressed by the title of "Doctor," and solicit d for a prescription. Of course there is nothing to do but to comply with the request, and both parties to the transaction are well pleased. The apothecary has a splendid opportunity for selling his medicine at a handsome profit, and the patient is very willing to pay for the same, because he gets his consultation for nothing. We can hardly blame an ignorant patient for failing to make out the distinction between a pharmacist proper and a regularly qualified physician, as he has not yet learned that the two professions are not usually combined in the same individual: but how can we excuse any fair-minded, honorable gentleman for taking advantage of such ignorance?

It is useless to attempt to enumerate the many mistakes that are made by these prescribers, the countless errors in diagnosis, and the worse errors of treatment; but we wish to view the question in the light of ordinary equity to the medical profession. In one of the articles of the code of ethics, which is adopted by all the respectable pharmacists of this city, we would call attention to the following language: "Since the professional training of the pharmacist does not include those branches which enable the physician to diagnose and treat disease, we should, in all practicable cases, decline to give medical advice, and refer the applicant

to a regular physician." The strict and honorable interpretation of the spirit of this provision would leave very little to be desired in the shape of a remedy for the evil practices of which we complain. From the facts which are constantly presented to us, we have no hesitation in saying that any such interpretation of the code is an exception to the general rule. Either the majority of the druggists have very slim notions of their obligations in the premises, or there is no power to enforce the necessary discipline. Many of these individuals excuse the practice on the score of its necessity, and in consequence of the surrounding circumstances, over which they have no personal control. They plead in extenuation that they only attempt to advise in ordinary and simple cases, in which a physician would not be consulted: that the medicines administered are harmless, and that if some mixture was not "made up" for the patient a neighboring store would secure the customer. Fallacious as this argument really is, it is the only one which these apothecaries have to offer for encouraging a practice which they know to be wrong, and which they must acknowledge has a tendency, in an almost countless number of ways, of lessening the legitimate profits of the physician, and of destroying his influence in the community.

The position occupied by the druggist is a peculiarly responsible one, not only to the community, but to the medical profession. By the former he is generally looked upon as an adviser, and by the latter as a protector. He abuses both of these trusts when he attempts to prescribe for any who may seek such advice. He may give nothing but simple medicines, but is he, by so doing, conscientiously giving the patient the best possible chance? Is he sure that he may not be losing valuable time, even allowing that he has made a diagnosis of the disease? If the patient does not choose to consult a physician, what responsibility has the pharmacist in the matter? We would be willing to leave the matter at this point as one of conscience with the pharmacist, if our own interests were not too directly concerned. The truth, however, is, that by allowing the pernicious practice to continue, we practically deliver ourselves into the hands of unprincipled men, and, by patronizing them, help to encourage an enemy, who is the more dangerous as his practices are the more underhanded.

If these gentlemen do not find it to their interest to protect us by following the precepts of their own code, is it not time that we look around us for some change,—that we openly discourage our patients from purchasing their medicines of these prescribing shops,—in fact, take every other means to secure ordinary plain dealing. We would like to inquire of some of the right-minded pharmacists throughout the city and country if there is any tribunal to which our profession can appeal for justice in this matter, any power which these "counter doctors" are bound to respect?

OUR WATER SUPPLY.

WE regret that the *Herald* of the 3d inst. gave an entire page, with a large map, to a highly sensational article upon the alleged "Nuisances daily contaminating Croton Lake and its Tributaries." Of course, anything which relates to the purity or otherwise of our drinking-water is likely to attract the attention of the citizens of New York, and to be accepted very generally in proportion to the lack of actual knowledge and to the plausibility of the statements. If the facts were as represented it would be cause for general anxiety and alarm, notwithstanding the purification of the water in its forty-mile run to the city. It is well that the profession should know, however, that Croton Lake is well guarded against any contamination from its surroundings; no drains whatever, in the sewer sense of the word, empty into it; hardly an acre of swamp land can be found anywhere on its borders. The map referred to is not less than fifteen or twenty years old, and if, as stated, the Croton Water Department has no better, it has a very inaccurate and imperfect survey of its trust, and should be looked after by the Legislative Committee now looking into the management of our City Departments.

Reports of Societies.

Stated Meeting, Nov. 19, 1875.

DR. E. R. PEASLEE, PRESIDENT, IN THE CHAIR.

ON CERTAIN POINTS IN CONNECTION WITH THE NERVOUS SYSTEM OF CHILDREN.

DR. JACOBI, at the close of his remarks made at the last stated meeting, mentioned hysteria as occurring in children, and further stated that hysteria may occur independent of disease of the genital organs. He continued his remarks this evening by directing attention to the connection which exists between these hysterical symptoms and the blood-vessels, and general and local nutrition.

The blood-vessels in their spastic contractions, and it appears to be essentially the same in their dilations, show a number of symptoms in the young, frequently also in the adult, which appear, in part at least, to have escaped the attention of a number of observers.

We know that influences upon the vaso-motor system will result in either contraction or dilatation of the blood-vessels: the first result, irritation; the later result, paralysis. Whether the latter is positively true cannot be said. When we remember that frequently the so-called reflex paralyzes are said to be the result of irritation of peripheral parts, it strikes us at once that there is something anomalous in the idea that irritation of one part should result in paralysis by simply reflex influence in a distant part.

From what we now know of paralysis, or dilatation of blood-vessels, the doctor was of the opinion that a large number of the so-called cases of reflex paralysis are susceptible of a much easier explanation.

Now it has been found by German physiologists that dilatation of the blood-vessels is not always the result of paralysis of the corresponding nerve, but that it results also from the irritation of a number of nerves, taking their origin mostly in the spinal cord. That is, the lumen of the vessel is dilated, not in consequence of a paralytic condition, but in consequence of irritation. If this be true, perhaps a number of the so-called reflex paralyzes can be better explained than they have been heretofore. The vaso-motor nerves have a peculiar influence upon the entire vascular system or upon a part. Let us imagine that their influence has been exerted upon the blood-vessels of the brain, what is the result? Dilatation of the blood-vessels, stagnation of the circulation, insufficient nutrition, perhaps effusion. The opinion was expressed that a number of cases which are spoken of under the head of intellectual disturbances are nothing but congestion and dilatation of blood-vessels, with effusion.

For instance, the condition which is present at the base of the brain, as in melancholia; also the condition of probable effusion in little children, which we cannot explain, are not the result of local troubles, but are due to the influence exerted upon the vaso-motor system, and nothing else. In such cases probably all our absorbent remedies are of no use, because the original cause will not be removed by them. It is very probable that if we could succeed in stimulating the paralyzed motor nerves, we should be much more successful in the treatment of these cases.

Imagine, again, that such a paralyzing influence takes place upon the vaso-motor nerves supplying the vessels of the spinal cord. What would be the result? General and local dilatation of the blood-vessels. Of such local dilatation a small number of cases are upon record. There is, in consequence, an apparent hyperemia, a real anemia of neighboring parts, in consequence of the compression of the smaller blood-vessels, and there will be anomalies of nutrition.

In substantiation of this the following symptoms, developed in cases that fell under the doctor's observation in the German Hospital, were stated.

Two young men, between the ages of 18 and 25, were constipated for some time, suddenly discovered that they were unable to walk as well as usual; were a little heavy in the lower extremities, and all at once were paralyzed in a similar manner with the cases of so-called infantile paralysis. In one case there was tenderness over the spinous processes in the lumbar region. There was a certain debility of the bladder and rectum, but the sphincters were not altogether paralyzed.

One suffered from complete motor paralysis affecting the lower extremities, which lasted for a number of weeks. Both cases recovered under the use of ice to the spine, the internal use of ergot continued for some time, and the bi-daily use of the galvanic current.

There was at no time in their history any increase of temperature, and the doctor was of the opinion that both were cases in which there was present simply an abnormal condition of the blood-vessels of the cord, undoubtedly a dilatation. He also related a similar case occurring in a girl, 10½ years of age, in whom there was nearly complete motor paralysis of the lower extremities, absolutely without fever. Local territories of hyperemia, especially about the head and face, were frequently seen. More frequently, however, spots of localized anemia were developed. Perspiration was free upon the spots of local hyperemia, while the remainder of the limbs were cool and dry. In a number of places local hyperesthesia was present; generally in the immediate neighborhood of the localized

injections. Localities where there was anaesthesia were just as extensive as were the localized hyperaemias, and there were days when the anaesthesia was general.

Local redness could be produced at will upon any part of the body by rubbing, the same as seen in meningitis where it is so frequently attributed to paralysis of the vaso-motor nerves, and considered one of the directly dangerous symptoms of a tubercular meningitis. These spots would remain five or six minutes after being developed. It is true that in a number of instances the same symptom has been found in typhoid fever, in severe cases of pneumonia, but they have been found only in those cases in which the general system is very much reduced, and vaso-motor paralysis has been established.

When lying upon the back the girl could move the legs and thighs to a very limited extent, and could bring them up with a sort of swinging movement.

Another case was related in which local anaesthesia was developed in a boy aet. 14 years. He would swing the leg he wished to move in a half circle. No history of masturbation could be traced. There was slight sensitiveness over the lumbar spines. The case was mentioned for a special reason, namely, because the change in the blood-vessels supposed to be present yielded so directly to the treatment instituted, and the result was a recovery from the hyperaesthesia and anaesthesia, and also from the symptoms of intense abdominal pain and nausea which had troubled him for a long time. Quinine, ergotine, and the continued use of the galvanic current were the measures adopted. 4

Thus it appears that irregularities in action of the vaso-motor nerves are sufficient to develop a paralysis which will find no explanation in either inflammatory changes affecting the spinal cord, or in any other well-known cause of paralysis. These are results which may follow dilatation of blood-vessels in the brain and spinal cord.

What takes place when we have to deal with paralysis of vaso-motor nerves in the skin? I shall not now speak of *herpes zoster*, which by common consent is regarded as a nervous disease, but shall confine what I have to say to the influence which dilated blood-vessels may have in those cases named *URTICARIA* AND *PEMPHIGUS*. Here the doctor referred to the pathology of the two affections, and incidentally remarked that he did not believe pemphigus to be syphilitic in every case. If found in the palm of the hand or sole of the foot it is probably syphilitic. But in a majority of the cases occurring in the new-born, in whom the disease is of most frequent occurrence, it is not syphilitic. Some celebrated authors have denied the occurrence of acute pemphigus. Hebra says that he has not seen a case of acute pemphigus in a million of sick persons, and therefore doubts the diagnosis in those which have been reported.

A case was then related as evidence that pemphigus may occur as a nervous disease. A child, 4 years of age, when first visited by the doctor, had a temperature of 104 or 5° F., a pulse numbering 150 or 160; was delirious, and died the following day. When the attending physician was first called there were present some slight red marks over the face and lower extremities. The next day these spots had enlarged, and were a little darker in color. On the following day some of these red marks were covered with small vesicles, and the fever appeared to increase rather than to diminish. Within twenty-four hours from that time almost the entire body was covered, not with small, but with large vesicles, varying in size from a pin's-head to a bean, or even larger. Diagnosis of pemphigus was made. The child had never had pemphigus be-

fore. The surface was in the following condition: There was not a particle of healthy skin over the entire body. Hundreds of vesicles had not been broken, and very many had been ruptured. When the surface was touched the epidermis was removed by the finger. As a consequence much of the surface was unavoidably denuded of its epidermis. The case could not be explained except as being due to some general cause.

The doctor then thought of irritation or paralysis of nerve centres, and studied the previous history of the case. There had been no spasms. There was no history of nervous diseases in the family; no history of neuralgias. But the fact was finally brought out that the child had been an unusual sufferer from urticaria; scarcely a day passing but what he suffered more or less from it; and he could develop an urticarous eruption by scratching at any time. He was probably not free from the urticaria more than two or three days at any one time. The case was then regarded as one of pemphigus developed upon urticaria, and attended by a fatal result.

Another member of the family had *hives* very much. The father of the child had been troubled with hives almost constantly during the year and a half past. A brother of the father complained of hives almost his entire lifetime; but not to such an extent as it had been manifest in the children of this family.

The case was finally regarded as one of acute pemphigus, and dependent upon the action of the vaso-motor system, finally resulting in a general effusion and death.

If this paralysis of blood-vessels takes place in the upper part of the body, and affects the thyroid veins and the veins which supply the orbit, there will be a protrusion of the eye, a swelling of the thyroid gland, and we have developed the disease which has received the name,

EXOPHTHALMIC GOITRE.

The very fact that the symptoms of this disease depend upon disturbances affecting the heart, the thyroid gland, and the eye, distinct parts of the body, is sufficient to incite us to search for some general cause.

Graves' disease, as it is also called, is not always easily diagnosticated. There are cases in which the chief symptoms present are referable to the heart; or there may be heart anomalies with goitre, and but little exophthalmos; or there may be a slight amount of goitre and a good deal of exophthalmos.

The doctor alluded to two cases occurring in children and presenting as well-marked features as in the adult. In one case the goitre was most marked upon the right side, which was regarded as somewhat exceptional, and there was only slight protrusion of the eyes. Iron, digitaline, and ergot were continued for some time, and recovery was complete in both cases. In both cases valvular murmurs were present.

When we assume that the blood-vessels are in this anomalous condition, and remain so for some time, what is the result as far as nutrition goes?

Certain hypertrophies occasionally, or atrophy, must be produced.

Hypertrophy may take place in the following manner: there is hyperaemia, stagnation, effusion, and in consequence of that the neighboring tissues swell, and finally increase.

Clubbed phalanges, with incurved nails, are explained in this manner, and are the direct result of venous stagnation. There are certain cases in which there is a marked unilateral increase of connective tissue, occurring mostly in males. Probably all these cases are to be explained by the presence of anomalies in the

circulation. Reference in this connection was made to unilateral atrophy of the face and extremities, principally found in children under fifteen years of age. Most of these cases occur upon the left side of the body. This feature is very probably explained by the fact that the right side of the brain is the feebler one. The right side of the body is stronger than the left, not from habit, but from the natural fact that there is a peculiar arrangement of the blood-vessels which furnishes the left side of the brain with more food. The direct admission of blood through the carotid to the left side of the brain appears to be sufficient reason why it should be more favored than the right, and therefore the right side of the body more developed. It may therefore be alleged as a reason why atrophy is especially apt to be found upon the left side of the body, because the right side of the brain is the less fully supplied with blood, consequently receives less nourishment.

The doctor here referred to a case of a child in which there was atrophy of the entire left side of the body. Perhaps there was an original defect in this case in the right side of the brain; but the left half of the head was smaller than the right. Probably this case could be explained by a difference in the development of the arterial system upon either side. There is a peculiar anatomical point which is of importance while studying these anomalies. The doctor was of the opinion that childhood is morbidly liable to the changes under consideration for the following anatomical reasons: In the embryo the nerve-cells are first developed. This is true both of the brain and spinal cord. These sympathetic cells and ganglia, which are found in the nervous centres, are of the earliest development. In the spinal cord this occurs earliest in the anterior horns.

It may be that the slightest changes in the first development of these parts is of prime importance as affecting the subsequent development of the blood-vessels, consequently influences the nutrition of the several parts to which they are distributed.

DR. LAWS reported a case of unilateral atrophy, discovered in the dissecting-room, in which there was a marked diminution in the size of the right arm as compared with the left, and when the hemispheres of the brain were removed, it was found that the left weighed one ounce less than the right. The immediate explanation was found in the fact that the left carotid was absent. The case was mentioned to illustrate the importance of post-mortem in determining the cause in anomalous cases. It is quite probable that the case referred to, if it had been seen during life, would have been explained upon some other hypothesis.

DR. A. McL. HAMILTON expressed the opinion that perhaps the so-called pseudo-hypertrophic paralysis may be explained by some abnormality in the function of the sympathetic nervous system of the character to which Dr. Jacobi has made reference. Inasmuch as there has not been found any change in the spinal cord to account for this condition, it is not unreasonable to suppose that it may be due to some continued disorder of the functions of the nerves.

It is quite probable that very many nervous diseases, now obscure, will finally be explained upon the basis of disturbances affecting the sympathetic nervous system.

DR. JACOBI remarked that the hypertrophy of muscles alluded to by Dr. Hamilton should not be placed here. For there is present fatty degeneration, especially of the connective tissue, and the large bulk of the muscle seen is rather apparent, and not so much because there is any additional amount of muscular

tissue, as to a change affecting another part; but the muscle is not increased, is not actually stronger.

DR. HAMILTON thought it quite probable that the first changes that occurred—those prior to any perceptible change in the muscle itself—are due to some change affecting the nerves.

DR. McLVAINÉ inquired of Dr. Jacobi what the symptoms were in the two cases which he reported as dying from *uræmia* after taking chlorate of potassa.

DR. JACOBI replied that perhaps he had used the word *uræmia* unadvisedly, and wished to be understood as saying that his patients had acute nephritis. For what *uræmia* is we do not know. The symptoms in these cases were, suppression of urine, complete for two days, pain over kidneys, high fever, rapid pulse, gradual diminution of mental and intellectual powers, and finally sopor, deep coma, and death.

DR. PEASLEE asked Dr. Jacobi whether he wished to be understood as saying that a patient who had had suppression of urine for two or three days, and finally died comatose, died from nephritis, or whether he regarded it as death from *uræmia*?

DR. JACOBI replied that he should regard it as death from *uræmia*.

DR. McLVAINÉ remarked that he accepted the explanation, but denied the truthfulness of the statement that patients died from *uræmia*. He did not believe there was any such thing as *uræmia*.

The remainder of the evening was occupied by the reading of a note upon *gout*, by Dr. Carroll, and subsequent remarks by Dr. Wm. H. Draper.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 10, 1875.

DR. F. DELAFIELD, PRESIDENT, IN THE CHAIR.

TAPEWORM TREATED BY BALSAM COPAIBA.

DR. CARO presented a tapeworm fifty-three inches long, which had been expelled from a male patient under somewhat peculiar circumstances. The gentleman had been suffering with symptoms of tapeworm for a number of years, during which time he had made trial of all the usual remedies for their relief. Last September he applied to Dr. C. for the treatment of a gleet discharge. Balsam copaiba was prescribed in large doses ($\frac{5}{8}$ ss every four hours until the bowels were freely evacuated). The first dose had the desired effect, and to his surprise the worm was evacuated entire. Dr. C. was not aware that this remedy had ever been used before with such a result.

DR. BRIDGON had never failed in the treatment of tapeworm by the use of the ethereal extract of malefern. His usual plan was to administer the black draught, followed for twenty-four hours with nothing but beef tea; then from a drachm to two drachms of ethereal extract of malefern, and twelve hours afterwards a dose of castor oil.

CRIMINAL ABORTION—ARE THERE ANY EVIDENCES OF THE SAME THREE WEEKS AFTER THE OPERATION?

DR. FINNELL exhibited the genitalia of a female aged twenty-five years, who had been the victim of criminal abortion. Finding herself about two months pregnant, she consulted a professional abortionist for relief. He administered several doses of cathartic medicine, without, however, producing the effect which he desired. On the occasion of a subsequent application for relief, instruments were used, when peritonitis developed itself, of which she finally died three weeks afterwards. The autopsy was made at the instance of the coroner. The abdomen was found

intensely distended with gas, and a large quantity of sero-purulent matter exuded from the incision in the abdominal walls. The intestines were more or less matted together, and presented other evidences of peritonitis. The uterus was somewhat enlarged, measuring five inches in its long diameter, and four inches in its short diameter. The length of its internal cavity was three and a half inches; the greatest thickness of the walls being one inch. Its weight was three ounces. The remarkable point of the case was, that there were no evidences of abrasion about the cervix, nor any marks of a placental site. The left ovary contained a corpus luteum.

Three of the coroner's jury were medical men. Each was asked to give an opinion as to whether it was possible for instruments to be used in the production of abortion without leaving some marks behind; also whether it was possible for the womb to enlarge from other causes than pregnancy; and finally if it could be said that the woman had died of criminal abortion. The answers were affirmative.

DR. BRIDDOX asked Dr. Finnell if in his (Dr. F.'s) judgment the uterus had contained an ovum.

DR. FINNELL answered in the affirmative, giving as his reason therefor the enlargement of the organ.

DR. BRIDDOX—Would you rely on this fact alone? Does not the lining membrane of the organ show some characteristic changes?

DR. FINNELL—There had been time for all these changes to disappear, as death took place three weeks after the instruments were said to have been used.

DR. PUTNAM JACOBI's question in regard to the absence of a placental site was answered in the same way.

DR. DELAFIELD asked if there was any other way of explaining the peritonitis.

DR. FINNELL answered in the negative.

DR. DELAFIELD thought that the history of the case rendered it tolerably certain, in absence of testimony to the contrary, that the patient had died of peritonitis, the result of criminal abortion.

In answer to a question from Dr. Putnam-Jacobi, Dr. Finnell stated that it was not at all uncommon to find peritonitis following injuries to the uterus without those injuries being evident at the post-mortem.

DR. DELAFIELD agreed with this statement, and referred to a case in point, in which forcible dilatation of the uterus for the treatment of dysmenorrhœa was followed in the course of a week by peritonitis, and at the autopsy which naturally followed the latter, there were no evidences of uterine lesions.

DR. PUTNAM-JACOBI remarked that such a case would apparently give foundation to the theory that the inflammation of the peritoneum was propagated through the uterine lymphatics.

DR. DELAFIELD thought such a condition of things might be possible, but it was exceedingly hard to prove it.

SCROFULOUS TESTICLE.

DR. BRIDDOX presented a diseased testicle. In the absence of a minute examination of the structure, he was unable to say whether it was the result of scrofulous degeneration or that of simple orchitis. The history of the case was as follows:

A man thirty-four years old suffered a severe contusion of his testicle two years ago. This accident was followed by acute inflammation, which resulted in suppuration at the end of two or three weeks, and perforation of the walls of the scrotum. A discharge continued in the opening thus formed up to the time of the patient's admission into the Sixty-fourth Street Hospital. His treatment during the two years referred to had

been for the most part irregular, and having finally presented himself to one of the dispensaries of this city, he was advised to go to a hospital and have the organ removed. When Dr. Briddon first saw him, he learned that the patient's father and several relatives had died of phthisis. The patient himself had no signs of tuberculous disease, and regarded himself as a tolerably healthy man. His principal annoyance was the intolerably fetid discharge from the scrotal opening. On examination, the right scrotum was filled with a globular mass, which at different parts was adherent to the integument. There were also sinuses communicating with the interior of the organ, and the cord was enlarged, and its component parts matted together.

The operation of extirpation was performed October 31st. On incising the mass, about an ounce of terribly fetid pus was evacuated. There had evidently existed two cavities in the substance of the organ, but these by the destruction of the partition wall had become one, the indirect communication of which with the external opening accounted for the extreme fetor of the discharge.

The Society then went into executive session.

Correspondence.

THE RELATIONS OF MEDICAL MEN TO HOSPITALS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Without at all taking sides on the great questions which now agitate the medical profession, and that portion of the public who are interested in the affairs of the Lenox Hospital, I beg leave to say a few words on the subject in general—the relations of medical men to hospitals.

There seems to be no doubt as to the advantage to them of connection with these institutions, and perhaps they do not overrate these advantages. But there is an eagerness and an earnestness in seeking these positions which amount to importunity, and which can hardly fail to put them in a false position with regard to the trustees of the institutions.

This rule is not invariable, but it is too general. There are men who quietly take the places assigned them upon their own merits, but there are many others who are not content to wait for the success which will surely come. The aim of a physician or surgeon ought to be to make himself such a man that the hospital cannot do without him.

Is it not this bowing, not to say bending, to trustees which leads to the speaking of them with regard to the managers of a hospital as "subordinates"? Can any self-respecting man take a place where he is held to be a dependent and inferior, subject to the will or dictation of men who know nothing of his profession, and have slender means of judging of him? Have not doctors brought some of these things upon themselves?

On the other hand, the trustees of a hospital need to remember that the success of the institution depends upon its doctors; they are utterly helpless unless they have good physicians and surgeons. The mere M.D. is nothing: it is the skill and reputation.

And the whole public might safely amend its way of looking at doctors. They are too often sent for, and called upon, at all times and seasons, with less regard to their comfort than would be shown to a servant. Still, that is what they expect, we are told, and they make up their minds to have no life of their

own. But it is unfortunate for them and their profession when, in their eagerness for place or business, they forfeit their self-respect.

A LOOKER-ON.

DR. E. R. PULLING'S FUNIS CLAMP.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Some discussion has arisen over my "funis clamp," described in No. 245 of the RECORD, and also on the general subject of ligation of the umbilical cord. I take the first opportunity which has occurred since the appearance of Dr. Bayles' second communication (on Oct. 23d), to give my reasons for preferring the special mode of compressing the funis which I recommended, and the particular form of safety clamp which I adopted. Such an explanation would have accompanied my former article, but its necessity only became apparent to me after reading the correspondence of Drs. Bayles and Rose in Nos. 251, 257, and 259.

I cannot ignore the importance of a subject which at first perhaps seems almost trivial, while I am conscious that a certain number of new-born infants (I am afraid to guess how many) perish annually from hemorrhage resulting from imperfectly secured umbilical vessels. Of course, such accidents occurring after the careful application of the time-honored ligature of twine are rare, arising only in cases where the blood remains fluid, after the ligatures become loose and expose the pervious vessels to the full force of the heart's action. To meet the requirements of these exceptional cases we need a compressing agent competent to withstand this force. Its efficiency may be tested by applying it to a funis, the vessels of which are artificially distended with fluid, under a pressure greater than that of the blood in the arteries. It must stand this crucial test or it is worse than useless, inspiring false confidence and leading to neglect of watchful precaution. We test it, as the strength of a bridge is tested, beyond its probable requirements. Moreover, to attain perfect security we must employ it in all cases, since we cannot be quite certain beforehand whether we have a hemorrhagic condition to deal with.

Before adopting the safety clamp formerly described, I made careful and repeated experiments to ascertain the degree of compression required to render the vessels of the cord impervious *and to keep them so*, when subjected to distention by a column of fluid representing the maximum of the cardiac contractions. A section of fresh funis, having its vessels well washed out, was enclosed at one end by the clamp or ligature to be tested; in the vessels at the opposite end were secured small nozzles, which communicated with rubber tubes, which in turn were connected with a movable reservoir capable of being raised to the height of ten feet above the experimental section of cord, and this was subjected to the pressure of these columns of water for six hours. As the result of experiments like the foregoing, I found that I could obtain the requisite conditions of security and simplicity by using a clamp with flat surfaces half an inch wide, which, when in contact, gave a pressure of not less than four pounds avoirdupois, and which allowed a separation in the centre of one-third of an inch without unlocking. I further ascertained that the amount of force with which these surfaces must be approximated in order to render the vessels impermeable under the pressure used, must always be sufficient to cause the rapid and complete expulsion of the gelatine of the cord from the constricted portion, leaving nothing but its coverings and its vessels—an aggregate thickness usually no greater than that of writing paper. Removing the clamp and pressing this por-

tion into a cylinder, its diameter is sometimes found to be less than two millimetres. The impossibility of exerting effective pressure on so small an object with rubber rings is obvious. When they were substituted for the clamp in some recent experiments, applied as recommended by Dr. Bayles and rendered as secure as possible, I found that only two out of five resisted a pressure of ten feet of water more than a few seconds, and in them the vessels became permeable in less than a quarter of an hour. Even under five feet, none were controlled for an hour, the latter pressure being, I suppose, less than the ordinary force of the heart.

I do not deny that these rings will *generally* answer well enough, and so will an ordinary string. So will divulsing the cord, or pinching its severed end for a short time, till coagula form and become fixed in the vessels. Fifteen minutes' compression is usually enough to prevent hemorrhage, all subsequent constriction being dispensed with. So firm is the clot formed, even during the few minutes intervening between birth and division of the funis, that we frequently find it difficult to wash out the vessels of a short section of it by injecting them immediately afterwards.

The funis commonly receives less than an hour's constriction, for if the ordinary ligatures be examined at the end of this period, more than half of them will be found loose enough to permit the escape of fluid. In most mammals the cord is rendered secure by being broken, and it is interesting to know that this is the usual result of its divulsion in man. The vessels retract within the Whartonian gelatine which covers their orifices, and appears to facilitate the formation of a clot, the blood generally coagulating quickly when brought in contact with it. I may remark, that I base this conclusion chiefly on experiments which I made in the New York Lying-in Asylum, during 1854, at the suggestion of my predecessor, the late Dr. George T. Elliot.

With all deference to Drs. Bayles and Rose, both appear to have ignored the only valid reason that I know of for ligating the placental end of the funis—that is, the possible existence of a second fetus connected with the first through a single placenta, to which the two cords, connected by anastomosing vessels, are attached. Of course, the "*factus cruditus*," which "we veterans" of the profession acquire, enables us instantly to detect the presence or absence of a twin *in utero*. Even our professional glance, falling on the new-born infant, tells us whether in has a fellow; but let us not forget the lessons of caution, which I hope Alma Mater impresses on the younger, as she has done on the elder members of our profession, and which have sometimes been useful in the days when our faces, like our diplomas, were fresh and unwrinkled.

During the first two years of my practice, my blind adhesion to the rule of ligating the placental end of the funis, without waiting to ascertain its actual necessity, possibly saved two lives: for, in two cases the umbilical vessels of twins, attached to a single placenta, anastomosed so freely, that water injected into the vein of one cord escaped by a full stream by that of the other. Even now I usually secure the placental end of the cord until I have leisure to examine the womb carefully, after which I make an incision above the ligature, and let the blood escape. A few ounces, more or less, of fluid in the bed can surely be of little consequence; but those who, with one of my critics, think otherwise, may easily receive the flow from the funis, in a vessel kept in every well-regulated bed-chamber, prior to depositing the secundines in the same receptacle.

EZRA R. PULLING, M.D.

VETERINARY MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—As I am a constant reader of your valuable journal, and oftentimes receive valuable suggestions from its pages, I now take the liberty of offering you a few lines, not so much in defence, probably, as to bring the subject up for thought. Under the super-scription of *Unsuccessful Practitioners*, several letters have been written for and against Diploma's views or experience. The letter which I wish to call your attention to is in answer to M. D. V. S.

This gentleman, probably without *malice*, and undoubtedly without any knowledge of his subject, has written a letter in condemnation of the very principles he intends to uphold. I fully concur in his ideas relative to the diversity of ways in the dispensation of medical knowledge; at the same time I cannot concur in his remarks relative to veterinary medicine.

Nor can I understand why he ignores veterinary medicine. Is it not a science? Are not its principles common with those of any other specialty of medicine. Does he ignore oculists, surgeons, or obstetricians? They are specialists, yet have common principles, and hence are inseparable. It is not from personal feelings alone that I make these remarks (though I have probably more cause for being *insulted* than he had from M. D. V. S.'s letter); but, because I feel the want of professional appreciation by those who should know its value most. Every man who chooses *medicine* as a *profession* should not refuse to acknowledge its principles wherever seen. It is impossible for any one mind to compass all *that* is known or will be known relative to medicine; consequently, as a natural result we have what are known as *specialties*. But as the great principles of medicine are common to these specialties it is impossible to isolate them. *Veterinary medicine* is as much a *specialty* of *general medicine* as obstetrics is, and inseparably so, since anatomy and physiology are their common parents; and since the *laws* of health and disease are common to the animal *bodies*, why should not *therapeutics* be also? or, why more so in one than another?

It has always been my great pride to obtain medical knowledge wherever and by any means I could. Though it is impossible for me to practise *all the specialties*, I fully appreciate the great accumulation of knowledge therefrom, and the cultivation of which conduces to the one *great object*, the *progress of medicine*. Render unto Caesar the things which are Caesars.

Most respectfully, V. S.

TO THE EDITOR OF THE MEDICAL RECORD.

STR:—When in my letter, published in the RECORD, I advised Diploma to become a veterinarian, I never dreamt that it could give "such a shock" to your correspondent, E. N. R. O., etc., etc., and raise his furore to such a point as to make him issue such a long complaint against all specialties of medicine.

Since the publication of his letter I have looked for other expressions of the views of members of the profession, but none have made their appearance; and I think I can say that even with his "degree," it is remarkable that he seems to be the only one who views my letter as he did.

Such being the case, I might, taking the letter for whence it comes from, let the subject drop; but though I do not wish to open a controversy, I feel in duty bound for the welfare of my profession to answer *once for all*.

I would first ask from your correspondent if he has read that "shocking" letter of mine, and if so where has he seen that I recommend Diploma to become a "horse-doctor"? Does E. N. R. O., etc., etc., know the difference between the veterinarian and the horse-doctor; or does he judge them only by those with which he has come in contact? It is true that the veterinary surgeon must be a horse-doctor as well as a cow-doctor; but let me tell him that the latter cannot be the former, and for his special benefit allow me to inform him of what scientific studies the curriculum of veterinary learnings consist.

In all veterinary schools of Europe, if he will permit me to take them as guides, the students of that specialty have to study anatomy, physiology, chemistry, physics, pathology, surgery, obstetrics, pharmacy, therapeutics, hygiene, botany, zoology, jurisprudence, sanitary medicine; and the special branches of medicine do not apply to only one species of living beings, but to all the domestic animals; that is, to several different forms of organism.

Again, which is the most difficult, which of the two requires the closest attention and observation of the physician, who has to deal with a patient who can speak, who can tell his sufferings, and describe his symptoms, or of the veterinarian who has to make his diagnosis before what we might call a deaf and dumb brute. Let him remember that in the practice of the diseases of children or of invalids how often he has been placed in the veterinarian's position, and how often he has been puzzled, though he was aided by what information he could obtain from an anxious mother or from a watchful nurse.

No. Mr. Editor, E. N. R. O., etc., etc., has not taken all these facts into consideration—he did not know them. The time is yet for him when the "honor of belonging to a learned profession" was represented by a serious face, a long and heavy white wig, a heavy long cane, and a pair of spectacles on the nose to crown the likeness; and for him beyond his title of doctor *medicinar* there is nothing.

What, to speak of our days, men like Bouley, Reynal, Lafosse, Colin, Chiauveau, who are members of the Academy of Medicine, of the Academy of Sciences of Paris; men like Williams, Ganguee, Spooner, Simonds; like Guret, Gerlack, and hundred of others, would dare to put themselves on his level. No; stand back, all of you; stand back, you are nothing but "horse-doctors"—your works, your writings are nothing. E. N. R. O., etc., etc., is yet living, and you are insulting him in considering him a brother practitioner, your equal.

Begging your pardon, and that of your readers, for such a long answer, I remain, dear sir,

Yours truly,

M. D. V. S.

PUERPERAL FEVER.

THE following letter was addressed to Prof. Fordyce Barker, of this city, and will explain itself:

DEAR DOCTOR:—Pardon me for addressing you, but, having just read the remarks made by you before the New York County Medical Society upon Dr. Lusk's paper upon Puerperal Fever, I cannot resist the temptation.

During the winter of 1842-3 a very malignant form of erysipelas prevailed through the eastern and southern towns of this great county, but none in the northern or western towns. I had a brother who contracted it by attending a lady who had a premature labor, and who died of puerperal fever. The child had erysipelas

and died. My brother did not die, but he was confined to his room for six months, and did not fully recover for more than a year. In the early spring of 1843 I removed from the west part of the county, where there was no erysipelas, to the east part (Poitsdam), where the epidemic had prevailed to a fearful extent, and was still prevailing. During my six months' experience with this epidemic erysipelas more than fifty per cent. of confinements at full time were followed by puerperal fever, and of these more than fifty per cent. died. If a pregnant female was attacked with the erysipelas in any form, she was sure to miscarry and as sure to die. So palpable was this fact, and plain to laymen, that marriages that were contemplated and arranged for among the intelligent class, were indefinitely postponed, and were not consummated for more than a year after the epidemic had passed over.

Respectfully yours,

B. F. SHERMAN.

OGDENSBURG, ST. LAWRENCE CO., Nov. 5, 1875.

INUNCTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In an article on "Inunction" in your issue of the 30th ult., I notice that Dr. Angel attributes almost as much efficacy to the rubbing as to the substance used. Without doubt both are important, but I believe the greater benefit is derived from the nutrient qualities of the oil or unguent employed. I am convinced, from observation, that cod-liver oil is rapidly absorbed when it is thoroughly rubbed into the skin, especially if it is used immediately after a warm bath, or combined with chloroform, which materially aids in the absorption of any fatty matter. One of the worst cases of marasmus I ever saw—in which recovery was deemed hopeless—was restored to health by the frequent inunction of cod-liver oil, without a particle of medicine being given by the mouth.

In cholera infantum I have repeatedly seen its good effects in relieving the vomiting and diarrhoea, and I have no doubt that in the treatment of fevers, and of the exanthemata, it will prove a most potent agent for good.

The disagreeable odor of cod oil, and the tendency to rancidity in most animal and vegetable fats are, of course, objectionable, hence the superiority of vasoline; but in the oil of benne, expressed from the seeds of the *sesamum indicum*, will be found all the necessary qualities for inunction, as it is *nutrient, bland, inodorous, absorbable, free from gumminess*, and if benzoated or mixed with chloroform it will not become rancid from the heat of the body, nor from age or exposure.

C. J. CLEBORNE, M.D.

KITTERY, ME., Nov. 6, 1875.

SEVERE INJURIES DURING PREGNANCY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—A remarkable case of gestation occurred recently in my practice at 224 E. 19th Street. Mrs. K—, a German, aged 25 years, is of small frame, the mother of a child now two years old; has always enjoyed good health. On the evening of the 13th of August the patient was drawing in a line of wet garments, when it broke, precipitating her backwards into the yard, a distance of twenty-five feet, against a bluestone pavement, and striking on her left os calcis and right patella. I saw her a few minutes after

wards and found her recovering from the shock, with slight contusions. Ordered a sedative mixture and evaporating lotion. She was able to go about again in a few days, with only a soreness around the ankle. At the time of the fall she was in her seventh month of gestation. No unfavorable symptoms appeared, and on the 8th of October she was delivered of a vigorous boy, being sixty-one days from date of accident.

G. W. FRION, M.D.

345 E. 17TH STREET.

INDEPENDENCE IN MEDICAL TEACHING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Will you oblige me by informing A. M. D., through your columns, that the statements in his article in THE RECORD of Nov. 13, that "about one hundred ambitious physicians and surgeons of New York and Philadelphia, and half the same number in Boston, manage our Colleges for their profit, and a thousand or two others in the same cities calmly look on and are daily humiliated;" and that "it is easier to secure a diploma from the best medical college in the States than to learn to make a panel-door, etc.," are incorrect, so far as they concern one of the cities and colleges therein named.

There is a medical college in this country where the professors are paid fixed salaries only, and have no management of its finances and no direct interest in the amount or number of fees received from students; where the policy is to make the best and not the most doctors; where a systematic course of education is followed; where a student cannot even enter the second year until he has passed his examinations upon the studies of the first, nor gain his degree without passing in every one of the eleven required branches; where examinations are all conducted in writing, and judged without knowledge of personal relationship; where the examination papers are yearly published and distributed for the inspection of the profession; and finally, where, after another year, no student will be admitted unless he be a college graduate or pass a preliminary examination.

HARVARD.

BOSTON, November 19, 1875.

OUTWARD DISLOCATION OF FOREARM.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In addition to the cases of this injury reported by Dr. Andrews, of Bellevue, recently, and Dr. Variek, of Jersey City, in 1867, I desire to report a case in my practice. In June last a young man, aged 19 years, while playing at base-ball, fell and produced a complete dislocation of the left forearm outwards. He came to my office, and without assistance I reduced the dislocation, and the case did well. I had a similar case about the year 1868 or 1869.

Very respectfully,

A. B. BRUMBAUGH, M.D.

HUNTINGDON, PA., Oct. 25, 1875.

THE AMERICAN ACADEMY OF DENTAL SURGERY, of which Dr. Geo. H. Perrine, of this city, is the President, is in a very flourishing condition. Its meetings are held every month at the College of Physicians and Surgeons, and the papers presented are of great interest to the dentists.

THE PRESBYTERIAN HOSPITAL AFFAIR—A REPLY TO "CITIZEN."

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Will you kindly accord me a little space in your journal for the purpose of correcting sundry misstatements made by "CITIZEN" in your issue of December 4, 1875, No. 265.

"CITIZEN," in the first place, misconceives the object of the meeting, which he so pompously declares to be "simply ridiculous," and to which opinion, of course, he is perfectly welcome. Had he adopted the very simple, and what at first sight would seem the fairest plan, of waiting until the object of the meeting had been officially expressed, he would have saved himself from making the two blunders (to give it no worse name) into which he has fallen. But perhaps that would have been too much like fair play, and that would never have done.

In the first place, "CITIZEN" writes, "furthermore, any publicity that has been or may be given to the affair is due exclusively to the fact that the four gentlemen dropped, and their indiscreet friends, are trying to make a mere *private grief* a matter of *public notoriety*." (The italics are mine.) Had he waited only four days, he would have learned that "an affront had been offered to the profession, and physicians were not concerned with the persons who offered, or to whom was offered, the affront. It was for the defence of a certain principle that they had come together, and they should not let personal grievances influence them."—*Extract from the President's (Dr. Markoe's) Speech.*

Dr. Thomas in his speech reaffirmed the same sentiment, and, if anything, made it still more marked. He said, "You have all heard the exciting cause of this meeting, and let no one suppose that the large body of medical men before me now has been convened for the purpose of taking cognizance of the wrongs of a certain member of the profession. Far from it. He who imagines this, misconceives the object of the meeting, and belittles that object. A principle which interests our profession is at stake." Can language be plainer? In view of this declaration, what becomes of the charge of "trying to make a private grief a matter of public notoriety"?

Blunder No. 2.—After "CITIZEN" has uttered his bombastic opinion, that the call for the mass meeting of the medical profession is "simply ridiculous," he asks, "What right has the medical profession to dictate to the managers of this or any other hospital who their appointees shall be." No LEGAL RIGHT, "CITIZEN," has as yet been claimed by the "medical profession," so far as is known to the writer, and certainly not by the medical staff of the Presbyterian Hospital; for in the protest which six of the said staff signed, occurs this significant phrase, "We do not propose to question for a moment your legal right to elect to positions whomsoever you may think proper," etc.

Isn't "CITIZEN'S" conundrum sufficiently answered?

At the beginning of his letter "CITIZEN" starts off with a perversion of statement, viz.: "I notice in your valuable paper of date of November 27, 1875, No. 265,* two articles—one a communication from an ex-appointee of the Presbyterian Hospital, the other a call for a mass meeting of the medical profession of the city of New York—the burden of the complaint being an alleged act of injustice done to certain medical gentlemen, through the failure of the board

of managers to reappoint them on the medical staff of the hospital."

Let us first take up the last of the statements, or rather misstatements, advanced. Had "CITIZEN" read "the call for a mass meeting" with ordinary care and attention he would have seen that not one word is said about "injustice" done to any one. That is a gratuitous assumption on "CITIZEN'S" part, unsupported by any evidence so far as the wording of the "call" goes. This reads thus: "The members of the medical profession of the city of New York, who believe that the recent action of the Board of Managers of the Presbyterian Hospital, in the matter of failing to reappoint certain members of the medical staff, against whom no charges were preferred, is injurious to the hospitals in their beneficent work, are invited to meet at the theatre of the Union League Club, Tuesday evening, Nov. 30, at 8 o'clock, to give public expression to their views." Here follow the names.

Can "CITIZEN" find one word in the above about "injustice" by any one to any body?

The second article, viz., the "communication of an ex-appointee," is, in common with the other facts, distorted and warped to suit the views entertained by "CITIZEN." The object of the "ex-appointee," as "CITIZEN" so genially and politely styles Dr. Ward, who wrote the "communication," and whose name is signed thereto, was to correct "in the minds of some of your readers certain impressions which I know to be erroneous." And in but *one* place does the word "injustice" occur, and that in the following clause:

"At the June meeting of the board of managers, Drs. Peters, Allin, Stimson, Woodruff, and myself resigned our positions on the ground that an act of great injustice had been done to four of our former colleagues, in that they were 'dropped' without cause," etc.

Dr. Ward is certainly to be congratulated upon the success with which he has corrected erroneous impressions in the mind of *one citizen*, at least.

Upon page 814, not content, apparently, with his ingenious fictions, "CITIZEN" proceeds gravely to inform us that, "referring to the two articles in question, the burden of their complaint seems to be that four members of the medical staff were unjustly punished for voting for the man of their choice for the position of president of the medical board."

The "two articles in question" are "the call for a mass meeting," and the "communication from an ex-appointee." In the first one no allusion can be found to unjust punishment of any man or men "for voting for the man of their choice" for any position. I would recommend "CITIZEN" to search that call diligently. With regard to the second article, there is mention of such a thing, but couched in such language as to convey the idea (and as such intended, I believe), that to suppose for a moment the real reason of dropping these men was because they voted "for the man of their choice" was absurd, and I am surprised that this rendering of the sentence should have escaped "CITIZEN'S" acute mind. However, to give the full force of the sentence I must quote the paragraph entire from Dr. Ward's letter:

"At the regular meeting of the medical board in May, 1874, the ballot for president resulted in the election of a gentleman who had never before held the office. It has been stated that the board of managers were 'fairly incensed' at such independent conduct on the part of its medical staff. It would seem that such a statement must be greatly exaggerated, and I have heard it denied by more than one member of the board. Article 3, Section II., of the Rules and Regulations of the Hospital provides, that

* By the way, the number is 264, not 265. This is noted merely to point out how thoroughly in keeping the whole article is: inaccurate even to minutiae.

'the medical board, . . . at the first regular meeting, in May of each year, shall elect a president, vice-president,' etc. Each of your readers can decide for himself whether voting for the man of his choice is an offence for which he ought to be punished by being 'dropped' from the staff of a hospital."

"Citizen" admits that the medical staff had a "formal right" to elect their own president, "but," he asks, "had they the moral right?" He says that "Mr. Lenox earnestly wished and expected Dr. White to be continued in the position of President of the Medical Board," and goes on to state that "without reference to the capacity or superiority of Dr. White or his successor, one would naturally suppose that a decent regard for Mr. Lenox, as founder and patron of the hospital, and the man of all others whose wishes should be respected, would have induced the medical board, before dropping the man of Mr. Lenox's choice, to give some notice of their intention and their reasons for dropping him, and then give *him* the chance (which they claim for themselves) to resign if he wished so to do, or to have a hearing (as they claim they should have had)."

Here is a point which medical men would do well to think seriously upon. It is evidently expected that medical men shall have no "moral right" to elect as presiding officer any member of their boards except those who are pointed out as desirable to the lay board of managers. What, pray, would the non-medical board of managers of this hospital have thought if the medical men of the staff had expressed a wish that some one else should be elected president of their board than the present incumbent? "Citizen's" assertion that this was "the burden of their complaint" in the two articles is as flimsy as it is impertinent.

But, Mr. Editor, I have taken up as much space in your journal as I feel I ought, and in closing permit me to express a doubt, not unreasonable, I trust, that a board of managers which so conducts its business as to alienate from its hospital not only the larger part of its medical non-professional staff, but a respectable minority of its board, can hardly be said to "have the best interests of the institution in view," or to be "the proper parties to decide on all matters pertaining to the management of the institution."

Yours very sincerely,

FREDERICK R. STURGIS, M.D.

NEW YORK, December 5, 1875.

HOMEOPATHY IN THE UNIVERSITY OF MICHIGAN.

A NOTE FROM PROF. PALMER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In your journal just received, I find the following editorial statement:

"In answer to an inquiry of some of the students of the Medical Department of the Michigan University, Prof. Palmer is reported to have said in substance: 'With Dr. Sager it was a question of only two hundred dollars, while with us (the Faculty) it was a question of eighteen hundred dollars.'"

This report is entirely *false* in substance and in semblance, no such statement having been made by me as reported to you; and I ask for this explicit denial in your columns

Yours truly, A. B. PALMER.

[UNIVERSITY OF MICHIGAN, Dec. 3, 1875.

—We made the statement in the full belief of its absolute authenticity. We have asked our informant

for further proof, and until such arrives we willingly incline to the opinion that he has been mistaken in regard to the fact. In any event as a matter of justice to Prof. Palmer, we publish his denial without further delay.

G. F. S.

Medical Items and News.

THE LATE DR. E. KRACKOWIZER.—At the meeting of the New York Medical Journal Association the following was unanimously adopted:

Resolved. That we are deeply grieved at the death of our fellow, Dr. Ernest Krackowizer.

Dr. Krackowizer was in many respects a remarkable man. Endowed with more than ordinary natural talents, he had, by diligent study and with the aid of excellent opportunities, made himself one of the most advanced medical scholars of the country and of the age in which he lived. He was a man, also, of great practical tact and skill, of excellent judgment—always cautious and considerate, and yet possessed of sufficient courage and self-reliance for the greatest emergencies. He was withal modest, and this was the virtue which shone most conspicuously in his crown of diamonds, and which secured to him the love of all who knew him.

We feel his loss; and we tender to his family and to all who have been intimately related to, or associated with him, our profound sympathies.

PROF. JAMES H. ARMSBY, M.D., of Albany, died suddenly, Dec. 3, of pulmonary apoplexy. He was born in Sutton, Worcester Co., Mass., Dec. 31, 1809. His early education was derived from the public school of his native town. In 1830 he entered the office of the late Prof. March, of Albany, and in 1832 was made the Resident Physician of the Cholera Hospital, and made the first autopsy in that institution. While yet a student, he conceived the idea of the establishment of a hospital and medical college in Albany, and so successfully devoted his future energies in that direction, that they both became, principally through his instrumentalty, accomplished facts. He graduated in medicine at the Vermont Academy of Medicine in 1833, after which, in connection with his preceptor, he established a private medical school, which school was continued until the foundation of the medical college in which he took so active a part. In 1861 he was appointed U. S. Consul at Naples, a position which he creditably filled. While there he delivered popular scientific lectures, a practice which he continued with marked success after his return home. He received the honorary degree of A.M. from the Rochester University in 1836, and from Rutgers College in 1841. Prof. Armsby was married in 1841 to Anna L. Hawley, by whom he had a son and daughter. The wife and daughter died in 1846, and six years later the doctor married Miss Sarah Winne. She and one son, Gideon, survive him. From the foundation of the Albany Medical College until his death he was actively engaged as a teacher of Anatomy and Clinical Surgery. In both these departments he was signally successful, and the institution which he so long and so faithfully served will miss his disinterested zeal in its welfare, and his wise counsels in its management.

BACTERIA: THEIR NATURE, AND RELATION TO DISEASE.

By THOMAS E. SATTERTHWAITHE, M.D.,

SURGEON TO THE DEMILT DISPENSARY, ETC.

(A portion of this paper was read before the Medical Society of the County of New York, Nov. 22, 1875.)

PART I.

THERE is probably no medical question of the day that has attracted more general interest than that relating to the connection between certain minute organisms and disease—a subject upon which much labor has been expended and much has been written. It is the importance of such a question that has led to its being so closely scrutinized, since it forms the basis of one of the most complete theories that has ever been advanced to account for the origin and spread of certain diseases; and there is no doubt that if the relation of these minute bodies can be shown to be a *causal* one, our methods of treatment will have gained very much in simplicity and directness.

There is such a wonderful seductiveness in feeling that we have discovered the actual cause of disease, that we cannot but understand the enthusiasm with which the theory of a *contagium vivum seu animatum* has spread, and that its advocates have been numbered among the most prominent men of the day. Once having securely established such a doctrine, the practice of medicine will be many steps nearer to an exact science, for the nature and habits of the noxious principle being known, we may seek to eradicate it or render it inert, just as a chemist sets himself to eliminate or neutralize a known chemical substance.

But it has been our ignorance of just these first principles of diseased action that has been our stumbling-block for generations; for we cannot but confess, however unpleasant a reflection it may be upon us as a profession, that our progress has been very slow in this direction. Even in the most marked forms of such diseases as we know are propagated by a powerful poison of great endurance and power of multiplication, we have in comparatively few instances ascertained what the agent really is. There has, indeed, been no lack of theories to make up for such discrepancies in our knowledge; but most, if not all, have failed to produce any proof that has been accepted as completely satisfactory.

In saying this, however, it is not designed to infer that *no* progress has been made, for it is quite evident that we are gradually getting nearer and nearer to the real source of disease; and though we have often failed to find it, we have sometimes succeeded in showing the conditions under which it lives and thrives. This may be said of typhoid fever; for the researches of recent date have seemed to show conclusively that *foul drinking-water* and *the exhalations from privies and sewers, or their connections*, are the principal agencies by which the disease is spread.

That the real poison in all such infective diseases may be a living one, has at all times been a favorite idea; but whether, to use precise terms, living bodies hold the same relation to the diseases in question, as a certain fungous plant does to favus, or the itch-mite to the itch-disease, is a question that has exhibited uncommon difficulties in its solution. It is to investiga-

tions on these and kindred points that we invite inquiry.

How far back the attempt was made to get at the truth of these matters, we do not know; but we are told by Liebermeister that some of the early Roman authors* thought that malarial diseases were due to low organisms which in some way gained admittance into the system. But all of the old theories, whether merely wild and fanciful, or chancing to have a color of reality, were wholly without direct evidence in their favor, since their authors were without the necessary means for deciding such questions.

When, however, the microscope was discovered, there was a new turn in these matters, for it was soon afterwards shown by Leuwenhoek,† that such minute bodies as spermatozoa were to be found in the body, and so it was easy to see that other minute bodies might also circulate there. This idea received further confirmation from the experiments of Pasteur, who showed that fermentation was characterized by the growth and development of certain fungi, which had previously been known to exist in fermenting fluids, and which Pasteur affirmed were the essential factors in the production of fermentation.

With these definite notions as to the cause of fermentation, propounded by so brilliant an experimentalist, it was comparatively easy to assume that the processes of disease, which in so many respects, as to their period of incubation, rapid development, and often sudden decline, resemble the fermentation process, might also be produced by some such agents. This may serve to explain the origin of the term *zymotic*, or fermentative, the terms being interchangeable as applied to disease; the unknown agents were then, for similar reasons, called *ferments*.

It cannot be said, however, that the term *zymotic* has had anything but a very general application, for its precise limits have never been agreed upon. It came into use, however, with its companion *ferment*, as a convenient term to express conditions that were different in different minds, and in no case had any strong evidence as to their exact nature. By some, ferments have been regarded as independent organisms, with a life and existence separate and distinct from the body they were supposed to infect; by others, substances possibly of an inorganic nature; while by others again they have been held to be minute particles carried over from the diseased body to the one which was to be infected.

But the theory of independent organisms fell into disrepute when it was claimed by its zealous advocates that nearly every "catching" disease is due to a special organism. We may truly say that the theories as to the cause of malarial fevers, syphilis, and others we might mention, so far as they were claimed to be due to certain microscopic bodies, could not stand the close scrutiny which such subjects demand; for it was shown in such cases that the alleged bodies to be found in the contaminated blood were also present in the blood of healthy persons, if the bodies were not altogether an optical illusion. The alleged discoveries also of Hallier, a botanist of Jena, were proved to rest upon an equally insecure foundation; for while it might be admitted that he really found such bodies as he describes and represents in the instances he mentions, he does not show that he submitted them to a very necessary test: the successful inoculation of each and every form upon healthy subjects.‡

† *Loc. cit.*

‡ Sanderson, *British Med. Journal*, February 13, 1875.

While, therefore, these general doctrines have been received with distrust by many of those who have made these subjects matters of special inquiry, there still remained, and do still remain, a number of facts going to show that organisms of minute size may actually cause disease of themselves; for it has come to be settled that some diseases at least are due to minute animals, such, for example, as *scabies* and *trichinosis*, for the diseases in question can be produced by the introduction of these animals into the system, and, in the case of *scabies*, arrested by such means as kill the parasite.

So also botanists have come to an agreement that the silkworm disease is due to a special microscopic plant, while the epidemic diseases of cultivated plants, such as the potato disease or murrain, and the grape-vine disease*, are also due to growths of an analogous nature.* The same thing may be said in skin disease, for dermatologists are agreed that *favus* is due to a microscopic plant, and so, perhaps, of a large number of other skin diseases.

While, therefore, these facts rest upon a pretty secure foundation, we may safely say that in most of the epidemic diseases of man it has either been found that they exhibit in their lesions no specific organisms, or that at least they are not to be distinguished from those that are found under other circumstances. The majority of opinions has, therefore, been unfavorable to this *germ theory*, as it is called, and though here and there it has been maintained with some degree of force, public attention was not riveted on the precise points at issue until the researches of Chauveau,† Sanderson,‡ Bastian,§ Panum,|| Billroth,¶ and Hüller** came to be generally known. All of these observers admit that certain diseases are associated in their lesions with the presence of low organisms, and some of them (Chauveau, Sanderson) have shown that the relation is such a close one as to lead to the conclusion that they have to do with the cause of the disease. Are they, of course, a *necessary* cause, which is capable of the kind of demonstration that will place the matter beyond cavil? This, indeed, is the trying point of the controversy, and almost innumerable experiments have been made, though, we must admit, with conflicting results. There is no doubt that the matter presents extreme difficulties, some of which appear to be insurmountable; for it is not only requisite to have instruments of great power, but often an extreme delicacy of manipulation to be able to separate these minute substances completely from their combinations.

It will be the chief object of this paper to review some of the most important evidence that has been brought forward both for and against the "germ theory," and to record some experiments that have been done to throw light upon certain points in dispute.

We shall endeavor, first, however, to formulate what is known about the bodies alleged to constitute the *matrices morbi*—their form, structure, habitat, mode of life, and development. It may be as well to preface that they are all microscopic in size—some, indeed, so minute that it requires the highest powers of the microscope in common use to make them out with any degree of distinctness. It may also be said that the diseases to which they are related are all of the

kind that may in a general way be called *infective*, using the term in its broad sense—that is, such diseases as are either propagated by direct contact, or through the medium of the air, various gases, fluids, or common objects.

These bodies have recently come to be called *bacteria*, but they are not all rod-shaped, as the name* would imply. The name merely denotes the commonest of the forms that are met with. Bacteria are classed either as round or oval, or of dumb-bell form, rod-shaped or filamentous. They may be arranged in couples or in chains, in balls or in plates, or laminae. Some authors have described a great number of forms, but the classifications of Cohn and Billroth† are those that are generally accepted. That of the latter is somewhat the most complete, though, as will be seen, it embraces forms that are not met with in disease, but merely in fluids that have undergone various changes, so that, practically speaking, all of these bodies do not concern us.

To the round bodies Billroth gives the name "*coccus*," from the Greek, meaning a berry. His *micrococcus*, the smallest form, he finds only in putrid blood; the *mesococcus*, a larger spheroid, he finds in sour milk when it is not too old; the *megacoccus*, or largest spheroid, is found in concentrated meat infusions during the first 24-48 hours. When air has been admitted, the *coccus*, enveloped in a colloid mantle, unites with others to form a thin lamina or plate, which he then calls *petalococcus*; and then to irregular balls, which he calls *gliacoccus*. If air be withdrawn, the *gliacoccus* develops only sparingly. When the fluid is in motion, chains of various lengths (the *streptococcus*) are formed, together with balls, or *gliacoccus*. These chains are more or less spiral, and each joint divides, thus increasing the length of the chain.

Billroth also describes certain grayish-green club-shaped or cylindrical bodies (the *ascococcus*), which contain multitudes of *micrococcus* in a sort of gelatinous matrix. He has seen these curious bodies burst, and so deliver themselves of multitudes of *micrococcus*.‡

By *bacteria* Billroth means exclusively those bodies that are rod-shaped, and he enumerates three varieties or sizes of them, viz., *microbacteria*, *mesobacteria*, and *megabacteria*. They multiply by transverse division, or through certain bodies that he calls "*dauersporen*," or lasting-spores, as they have been called, particles that possess an extraordinary capacity for withstanding great heat, cold, and various reagents. These lasting spores are developed from the *gliacoccus* or balls. By long-continued growth and transverse division the long chains result. These forms thus sketched depend upon various influences, such as the lack or abundance of air, and the character of the media in which they exist. But, according to Billroth, they are merely parts of a common plant, which he calls *coccobacteria septica*, and which, in one instance, he found in an old specimen of milk serum.

The form of the mature plant would, according to Billroth, be analogous to that of some cryptogamic plants, of which the *penicillium*, or mould-fungus, is an example. Now, though we do not often see either of them in their fully developed state, yet under suitable conditions we know that one is seen, and it is not incredible that the other may also be seen. Thus, in the *penicillium* we see at the base the entwining net-

work of filaments that constitutes the *mycelium*, the tall, erect stem, or *hyphen*, surmounted by the globular expansion, with its staff-shaped *stigmata*, and finally its spherical *conidia*, or spores.

Such may, according to Billroth, be the relations of these minute bacterial bodies—rods, chains, and spheres—to a fully matured plant, which he has named *coccobacteria septica*.

The forms to which our attention is to be specially directed, are (a) the very minute little round bodies already described (micrococcus of Cohn, and coccobacteria of Billroth); (b) the little oval or elongated bodies which in length are about $\frac{1}{1000}$ of an inch, and about one-third the diameter of a lymphoid corpuscle, and have a breadth of about $\frac{1}{4000}$ of an inch; these are the bacteria proper; (c) the little chains which may have from two to ten segments, or even more (the streptococcus of Billroth); (d) the collections of minute spheroids that are gathered in balls (zoogloea of Cohn, colonies of Hallier, and gliacoccus of Billroth); (e) the filamentous bodies whose spiral motion is seen to great advantage in decomposing fluids, and which dart back and forth with a serpentine motion across the field of the microscope (spirillum of Cohn).* We

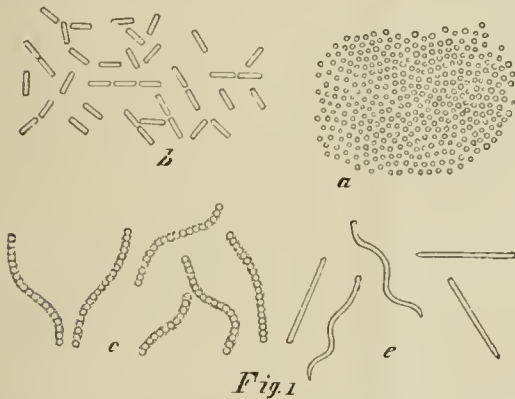

Fig. 1

shall find it convenient to use the term bacteria for all these forms—because the word has met with such common acceptance as comprehending the entire group just mentioned.

There are two conditions under which bacteria are found—one of motion, and the other of rest; the mere state of inaction not at all indicating that they are dead, for under the requisite conditions they may still grow and produce their kind. When in motion, the rod-bacteria have a sort of spiral movement on their long axis, along which they extend and contract; or they may spin about on the centre of their long diameter, or may move about with an oscillating movement. The smallest spheroids also move about within a limited area, but are often at rest, though it is by no means certain that they have the motion that is called "independent"—that is, one that they cause, rather than that which is caused by external circumstances. For the mere fact of motion in such particles does not indicate life; indeed all particles, even granules of any kind, may have a certain kind of oscillating movement, which depends on the density of the medium—for the denser the medium the more slowly they move. Real motion

in such bodies may be assured when they move against a current, or across it, and do not merely revolve about within a limited area. The spirilla have the most active motion; for they will dart across the field by a quick serpentine movement, often stop suddenly, and then dart off in the same or a different direction. When at rest they do not appear to be in spirals, as the drawings of them would often indicate, but they are straight and filamentous, the precise nature of their interior being uncertain.*

Bacteria have been supposed by some to possess an envelope of more density than ordinary protoplasm, as they are able to withstand extremes of heat and cold and the action of various reagents which dissolve protoplasmic matter very quickly. When these bodies occur in colonies, or in chains, or in plates, they are united by an extremely delicate cementing substance.

For a long time there was doubt as to whether bacteria were vegetable or animal, and the doubt does not appear to be altogether removed in some quarters; but botanists seem now to be pretty well united in considering them vegetable, and the following are some of the reasons for this opinion: They behave more like plants than animals, taking up nitrogen, which is often derived from ammonia, and carbon from almost any carbonaceous substance; they also need certain inorganic compounds, such as potash and phosphoric acid.† These facts were ascertained in an ingenious way by Cohn, of Breslau. Finding that bacteria grew rapidly in Pasteur's fluid, which has a determinate chemical composition, containing cane-sugar, tartrate of ammonia, yeast-ash, and water, he modified it in various ways, first throwing out the cane-sugar, which did not improve the liquid as a medium for bacteria, but only favored the growth of the sugar and mould fungi. Substituting for the yeast-ash sulphate of potassa and phosphate of potassa, he prepared his solution so as to contain:

Tartrate of ammonia.....	1.0 gramme.
Phosphate of potassa,	
Sulphate of magnesia, of each...	0.5 gramme.
Phosphate of lime.....	0.05 gramme.
Distilled water.....	100.0 c.c.

This fluid, now known as Cohn's nutrient fluid, when filtered, developed bacteria in enormous quantities, so that at the end of twenty-four hours it swarmed with them, and was distinctly turbid.

This was therefore in accordance with their vegetable nature, their nitrogen being taken from the ammonia, and their carbon from the tartrate. This fluid will not, however, originate bacteria of itself; for if it be boiled and put away in bent tubes that have been heated to redness, and whose necks have been drawn out to a fine point and sealed, it will remain clear indefinitely.

The same thing may be accomplished by stopping the mouth of a vertical tube with fine cotton; but if at any time the fluid be exposed to the air in an upright, unstoppered vessel, or if almost any substance not previously acted on by special reagents be brought in contact with the fluid, turbidity will then be sure to ensue within two days.

Another argument in favor of the vegetable nature of these bodies has recently been brought forward by Robin, the eminent French investigator. He rests his conclusions on ammonia.

Every form of cellulose, he says, is absolutely insoluble in ammonia, cold or boiling; every vegetable, microscopic or otherwise, every mycelium, and every

* This classification is a convenient one, and sufficiently accurate for the practical questions that at present concern us. There is little doubt but that many of the so-called micrococci are nothing but the rod-bacteria seen endwise; but spherical bodies are also sometimes found, and these, it is claimed, have been proved to originate rod bacteria.

† By some it is supposed that the spirilla are made up of spheres, though it is by no means certain that they all are similar in structure.
† Sanderou, Lancet, Jan. 16, 1875

spore retains integrally its form, volume, and structural character, while the reverse is the case with microscopic animals, their eggs and embryos. His ideas as to the relation the various forms we have described bear to the fully matured plant are not very unlike those of Billroth. Thus he says that when the little rods, which have been called bacteridia, microbacteria, etc., have attained a length of about $\frac{1}{1000}$ of an inch, they are known as the *leptothrix* (a common fungus found so frequently on the human tongue); they then represent mycelia; advancing to a higher stage they develop into articulate filaments, or perhaps into the spore-bearing tubes of the plant *oïdium* (which we know of from its association with thrush). They are cryptogams, like the penicillium, and can live with or without air. Thus two very prominent authorities connect these microscopic forms with certain cryptogamic plants, though they are not united as to what the ultimate complete plant is.* As to the way in which the smallest forms originate, we have no very definite knowledge. Billroth says that he has seen them pouring out of the capsules of the ascococcus, but this alone will not explain their appearance, for they sometimes are found where no such capsules are to be seen.

Rod-bacteria multiply by division, and these changes are exceedingly rapid when the conditions, such as fluid, temperature, etc., are favorable. Then each bacterium is said to divide in from one to two hours. Some of the smallest forms, however, appear suddenly in a fluid that was previously clear, and they soon show the characters of bacteria. The question of spontaneous generation in such cases is decidedly negated by the fact that if the fluid be boiled, and in this condition received into properly prepared vessels, no growth or appearance of it takes place; while, on the other hand, if almost any substance that has been exposed to the air at ordinary temperatures, or the air itself under certain conditions, be introduced, growth and multiplication will immediately take place.

Bacteria are found very abundantly in all putrid fluids and substances, with very rare, if any, exceptions; but they are by no means confined to such conditions, as they exist generally in nature, and, in fact, in the very air we breathe.† This may be demonstrated in the following simple way: If any one will take an ordinary glass slide that is rather thin, will superheat it, as well as the cover that is to be used, and expose the former to the ordinary dust of the room, and then examine the dust, with the addition of a single drop of distilled water that has previously been boiled, he will find, on using a good lens—such as an immersion 10th or 12th—that there are bodies present resembling the bacteria just described, and exhibiting such movements as we have stated that they have.

It is probable, therefore, that they exist among the notes seen in the sunbeam, as stated by Sanderson.‡ If epithelial scales can float about in the air, and be carried to the highest corners of rooms, as shown by my late preceptor, the distinguished Wyman, of Cambridge, why may not such minute objects as bacteria, so vastly more minute, be carried about in the same way?

[End of Part I.]

ST. LOUIS is to have a school of veterinary medicine.

A CASE OF INVERSION OF THE UTERUS, WITH OPERATION BY WHITE'S METHOD.

REPORTED BY ERNEST CLEVELAND COXE, M.D.,

BUFFALO, N. Y.

Mrs. C., aged 25 years, is a native of Allegany Co. She married when 18 years old, and had two confinements unmarked by any special incidents. On the 10th of June, 1875, she was brought to bed with her third child, and attended by a practitioner who for some time had discontinued professional business.

Dr. W. S. Cottrell, the physician now in charge, gives the following history of the case up to the date of the operation: "I was called to see Mrs. C. shortly after her delivery, the messenger stating that Dr. H. did not think that she could live five minutes. I immediately went to the house, and found the patient looking very badly; pale, in considerable pain; pulse 180, feeble in character. I asked the doctor if there had been flooding; he replied that there had not, and said that he attributed the pallor and prostration to the morphine which he had administered, gr. ij., within twenty minutes. Shortly afterwards she vomited the morphine, and expressed herself as feeling some better. The doctor in charge then stated to me that the child was born with the cord around its neck, and that the placenta and uterus came down at the same time with the child, that he detached the placenta, and returned the uterus. The women present say, however, that the child was born naturally, and that some time elapsed before the doctor 'took the after-birth,' and that at the time there was some organ visible which they had never seen before in confinements.

"The case was afterwards placed in my hands, and on visiting her four weeks after her delivery I found her very feeble in health, taking but little food, and that liquid in character. Nevertheless there was a large secretion of milk, on which the child thrived.

"Dr. Shaw, of Erie Co., being in the neighborhood, I determined to call him in consultation. Upon examination, a tumor was found lying in the vagina, which Dr. Shaw pronounced a uterine fibroid.

"This diagnosis was not satisfactory to me, so I sent for Dr. Crandall, of Andover, N. Y., to come in consultation, telling him to bring his instruments with him in case we should decide that it was fibroid. On examining the patient, Dr. Crandall gave as his opinion that the tumor was an inverted uterus.

"At this date, August 24th, Mrs. C. being fearfully reduced, and subject to very frequent hemorrhage, we decided that an operation for her relief should be attempted without delay."

Dr. Cottrell, at the request of the patient's husband, on the 9th of September wrote to Dr. White, asking him to operate. The doctor in reply named Sept. 22d as a convenient date, adding detailed directions in regard to preparing her for operation, *i.e.*, quinine and iron tonic, generous diet, perfect quiet, etc., laying particular stress upon the necessity of having the rectum thoroughly empty on the appointed day.

On Sept. 22d Dr. White arrived and proceeded to make his preliminary examination, the following gentlemen being present and assisting: Drs. Cottrell, of Whitesville; Crandall, of Andover; Coxe, of Buffalo; and Mr. Langworthy, a student.

The patient being fully under the influence of ether, Dr. White made an attempt to examine by means of the sound in the bladder and the finger in the rectum, but the condition of the latter viscus, which, in spite

of reiterated instruction, had been allowed to become loaded with hardened faeces, made this procedure impossible.

Upon introducing his finger into the vagina, the doctor was puzzled to find an object, which in shape and consistence, differed greatly from the organ which he was in search of. After careful manipulation, he was enabled to draw forth a ball of cotton cloth saturated with horridly offensive putrid blood and discharge. Quite a quantity of black tarry fluid followed the withdrawal of the wad, filling the room with a stench truly infernal.

Dr. Cottrell explained that two weeks previous, Mrs. C. having a severe attack of flooding, Dr. Crandall had found it necessary to tampon the vagina, using for the purpose four pieces of cotton cloth. He had left directions for him, Dr. Cottrell, to remove them on the following day. This, as he thought, he had done, but events proved that a portion of the tampon had been left *in situ* for a fortnight; the uterus, by its agency, during this period being freely bathed in a highly septic fluid.

After thoroughly syringing the vagina, the doctor was enabled to make a perfectly satisfactory diagnosis by conjoined manipulation. By pushing up the tumor, the inverted os could be plainly felt through the walls of the abdomen, which were relaxed and thin. The uterus was not large, showing that the process of involution had not been materially interfered with.

Introducing the right hand, armed with a large rectal bougie, into the vagina, while making counter-pressure with the left over the abdomen, partly by pressure, partly by manipulation, the walls of the uterus soon began to yield, and at the end of six minutes the doctor announced that the reduction was effected.

In this operation it was found unnecessary to use the "egg-beater" repositer. By comparing dates we find that the uterus had been inverted for three months and twelve days.

The patient rallied nicely from the ether, the pulse was good, appearance quite cheerful. Feeling a good deal of uterine tenesmus, morphine was administered and followed by relief.

Particular directions were then given in regard to antiseptic infections. Carbolic water to be used freely, quinine to be given in full doses, and all pain subdued by opiates.

Subsequent to the operation, symptoms of septicaemia showed themselves. These, however, yielded promptly to appropriate treatment, and this danger averted, the patient began to make rapid progress towards a good recovery. On the fifteenth day after the operation the menstrual flow appeared, continuing for two days. It was accompanied by the usual headache and slight abdominal pain, but no more than she was accustomed to experience at her "monthlies" before her pregnancy.

Eighteen days from date of operation the patient was able to sit up in a chair, ate with good appetite, and appeared so well that her attending physician discontinued his visits.

BOSTON HOSPITAL FOR WOMEN.—Boston has an institution similar to the New York State Woman's Hospital. It was opened on the 2d of November, at No. 16 East Springfield Street, and has accommodations for twenty patients. It is supported by churches and by individual charity, and is governed by a board of trustees and the medical staff. The nursing is by the Episcopal sisterhood of St. Margaret, and Dr. W. H. Baker is the Visiting Surgeon.

TRACHEOTOMY IN DIPHTHERIA, WITH RECOVERY.

By BEVERLIHOUT THOMPSON,

VISITING PHYSICIAN TO THE CENTRAL DISPENSARY; ONE OF THE ATTENDING PHYSICIANS TO THE OUTDOOR DEPARTMENT, BELLEVUE.

As comparatively few children recover from diphtheria after tracheotomy is resorted to, I consider it of sufficient interest to report the following case:

On the afternoon of the 4th of May, I was called to see the little daughter of Mrs. L—, aged five years—a small, delicate-looking child, with light hair and blue eyes; the mother said she had been unwell for several days; was feverish, very restless at night, and had a dry cough. The little girl appeared in good spirits; was running about the room playing, eating a cracker. I examined the chest carefully, but could detect nothing there to give rise to the cough; looked at the throat, which was filled with pieces of cracker—could see, however, that it was slightly congested; the tongue was moist and clean, the pulse a little excited, skin rather hot, appetite good, bowels regular; ordered a mixture containing tr. aconite, gr. xv.; potass. chloras, ℥ij.; spts. ætheris nitrici, ℥i.; syr. tolu. aquae cinnamon, aa ʒ iss. M. Dessert-spoonful every three hours, and promised to call in the morning.

At 9 p.m. was called again; found the child with a pulse of 120, a croupy cough, considerable dyspnoea, crying and tossing about in bed; discovered diphtheritic membrane commencing upon both tonsils; had the child put into a mustard bath up to the hips for a few minutes, and wrapped up in a blanket; gave tea-spoonful doses of syrup of ipecac every twenty minutes until vomiting was produced, when she became much easier; remained a half hour; pencilled the fauces with tr. iodine, and upon leaving ordered quiniæ sulph. gr. v., and sponges wrung out of hot water to be applied to the neck over the throat, should the breathing become difficult.

May 5th.—My morning visit was made at 10 a.m. The child had not slept during the night, having continued to grow worse; the membrane had extended over the fauces, the pulse 130, lips and finger-nails blue; there was alarming dyspnoea, and every appearance of immediate suffocation. An emetic of ipecac was administered; lime slacked until the room was filled with steam, the hot sponges applied, which afforded only temporary relief. The mother was informed of the danger; it was explained to her that it would be necessary to put a tube in the trachea, and a consultation was requested. I then arranged with Dr. Alfred L. Loomis to meet me at 12.15, and asked Dr. J. H. Dew to be present. After examining the child they both coincided with me in the opinion that tracheotomy was the only alternative, and stated to the mother the importance of the operation, which she consented to. Whereupon we proceeded to operate. An anæsthetic was not administered, as the child was nearly insensible. I made an incision through the integument in the median line, extending from the base of the cricoid cartilage to within half an inch of the sternum, divided the muscles and fasciæ, pushing aside several veins of the thyroid plexus, but the parts were so congested it was impossible to distinguish clearly, and a vein was unavoidably cut, which bled most profusely. I endeavored to tie it; was unsuccessful; used pressure; applied powdered alum, which was at hand. All my efforts, however, proving unavailing and the hemorrhage increasing to an alarming extent, Dr. Dew tried to arrest it, also Dr. Loomis. Suddenly the child gave a gasp, straightened herself out and ceased to breathe.

The mother, who had been standing by washing out the sponges as they were required, began to cry and wring her hands, exclaiming, "O, doctor, you have killed my child, you have killed my child; she has bled to death! Why didn't you let her die in peace?" Some little delay and confusion was occasioned by this interruption, as it really seemed almost useless to proceed further. Dr. Loomis, however, said, "Put in the tube." I seized my tenaculum, with which I steadied the trachea, and cut from above downwards, making an incision three-quarters of an inch in length, through which a silver tube was inserted, compressed the chest, forcing out frothy mucus and blood, when the child began to respire. A suture was passed down deeply through the tissues, above and below the tube, which controlled the hemorrhage, and in a short time respiration was fully established; the child was then given a little wine and water. 3.30 P.M. Pulse, 130; respiration, 48; temperature, 102°; has been dozing fifteen minutes at a time; made motions constantly for water; was given a little wine and water, also some milk punch. Ordered quinia sulph. gr. v. 9 P.M. Pulse, 132; respiration, 35; temperature, 102½°; expectorating considerably through the tube; has eaten a small piece of sponge cake and drank a cup of tea. Quinia sulph. gr. v., to be given at 10 P.M.; milk *ad libitum*.

6th, 9.30 A.M. Pulse, 134; respiration, 30; temperature, 102°. Slept during the night three-quarters of an hour at a time, drank one pint and a half of milk, voided urine, touched the parts around the tube with a weak solution of carbolic acid, ordered the steam from the slacked lime every three hours. Quinia sulph. gr. v., a saturated solution of hyposulphite of soda to be applied to the fauces with a camel's-hair brush three or four times a day. 4 P.M. Pulse, 125; respiration, 28; temperature, 102°. Very comfortable, bowels moved, taken a teacupful of chicken soup and a cup of milk; treatment continued. 10 P.M. Pulse 135; respiration, 43; temperature 102½°. Slept until 8 P.M., when she began to toss and struggle for breath. The dyspnoea was caused by thick, tenacious mucus collecting in and below the tube; the inner tube was removed by the mother to clean, and could not be returned, owing to the inspissated mucus. I succeeded in getting some of it out with a feather, but the paroxysms of difficult breathing soon returned. Administered quinia sulph. gr. v., kept up the steam from the lime continuously for two hours, left at 12 o'clock, promising to return; the tube to be kept clear with a feather. 1 A.M. Returned with Dr. Dew and Dr. Byrne. Pulse, 170; respiration, 25, and labored. Dr. Dew discovered subcrepitant râles over the infra-clavicular region of the right side; a spray of salt and water was applied to the tube without any appreciable benefit. A sponge wrung out in hot water and salt was then held near the tube, so as to allow the warm vapor to be inhaled, which softened the mucus and relieved the breathing greatly, the child in the meanwhile falling asleep; directed the sponges to be continued for five or six hours; ordered an oil-silk shirt.

7th, 8 A.M. Pulse, 132; respiration, 34; temperature, 101½°. Has slept nicely since half-past one, awakened once only for a few minutes and ate a small piece of banana, drank three teacupfuls of milk, expectorated several pieces of membrane through the tube, which were saved; prescribed quinia sulph. gr. v.; had the child removed to a larger room down stairs, with an open grate fire, the temperature of the room to be kept at 75°. 3 P.M. Called, accompanied with Dr. Beach. Pulse, 140; respiration, 25; temperature, 101½°. Took a teacup of milk, expectoration much looser, child coughed through the tube several pieces of diphtheri-

tic membrane, three to four inches in length, and from a quarter to one-half an inch in width, which were thrown out with considerable force; membrane still covering the fauces. Dr. Beach suggested that the feather be dipped in a saturated solution of bicarbonate of soda when clearing out the tube, because of its tendency to dissolve mucus. 10.30 P.M. Pulse, 130; respiration, 26; temperature, 102°. Has drunk two teacupfuls of milk, three tablespoonfuls of brandy and water; is sleeping very quietly, subcrepitant râles over infra-clavicular region of both sides. Quinia sulph. gr. v.

8th, Was sent for at 6 A.M. Pulse 140; respiration, 45; temperature, 101¾°. Tube almost closed with thickened mucus, could not be cleared, was obliged to remove it; the parts around the wound were cleansed with warm water and soap, the tube cleaned, well oiled, and returned with considerable difficulty; took through the night three teacupfuls of milk, three tablespoonfuls of brandy and water, and the leg of a pigeon; bowels moved, membrane in fauces cleaning off. Left at 8 A.M., child sitting up in bed playing. Pulse, 125; respiration, 35. 10 A.M. Respiration hurried, mucus collected below the tube, could not dislodge it with the feather, filled the room with steam from slacked lime, applied the hot sponges for two hours; several pieces of tough mucus were then coughed out, when the breathing was relieved; drank a cup of milk. Quinia sulph. gr. vi. 5 P.M. Pulse, 128; respiration, 44; temperature, 101¾°. Has drunk two cupfuls of milk, tablespoonful of brandy and water, eaten a small piece of custard pie and some currant jelly. Quinia sulph. gr. vi., to be given at 7 P.M. 10.30 P.M. Sleeping. Pulse, 128; respiration, 34; temperature, 101¾°. Drank two cupfuls of milk at six o'clock, which she vomited soon after; very little expectoration; ordered the sponges at intervals during the night held near the tube.

9th, 9 A.M. Pulse, 128; respiration, 24; temperature, 101¾°. Slept nearly all night; expectoration thinner, is coughed out of the tube freely; membrane in fauces entirely cleaned off; tongue moist and clean; lungs clear, râles having disappeared; there is some soreness and redness of the parts around the tube, to which a weak solution of carbolic acid is applied occasionally; taken one pint and three-quarters of milk, tablespoonful of brandy and water. 7 P.M. Pulse, 130; respiration, 32. Taken three ounces of wine, two pints and a half of milk, a piece of pigeon. Quinia sulph. gr. vi. 11 P.M. Pulse, 125; respiration, 46; temperature, 100°. Drank two ounces of wine, a pint and a half of milk; complains of earache; syringed ear with warm water, and put in a few drops of laudanum and olive oil; ordered quinia sulph. gr. iv. at 2 A.M.

10th, 9 A.M. Slept all night. Pulse, 108; respiration, 32; temperature, 99¾°. Very bright and playful; taken one pint of milk, one ounce of wine, a piece of pigeon. 10 P.M. Pulse, 108; respiration, 46; temperature, 100°. Taken a quart of milk, a cup of tea, and a piece of pigeon; ordered quinia sulph. gr. vi., at twelve o'clock.

11th, 10 A.M. Pulse, 112; respiration, 44; temperature, 98¾°. Rested well, ate a squab for breakfast, drank an ounce of wine and a cup of tea, is very lively, wants to get up, breathes through the mouth and nose when the tube is closed with the finger; discontinued the hyposulphite of soda to the fauces. 11.30 P.M. Pulse, 100; respiration, 40; temperature, 98¾°. Taken two squabs, three pints of milk, two ounces of wine; quinia sulph. gr. iv.

12th, 11 A.M. Pulse, 112; respiration, 48; temperature, 99°. Eaten a squab, drank one pint and a half

of milk, cup of tea, six ounces of wine; bowels moved after considerable straining and passed but little; ordered hydr. chloridi mite, pulv. rhei, $\bar{a}\bar{a}$ gr. ij. Removed the tube. 10 P.M. Pulse, 108; respiration, 44; temperature, 99°. Taken one pint of milk, twelve ounces of wine, small piece of pigeon; bowels moved; quinia sulph. gr. iv.

13th, 10.30 A.M. Pulse, 115; respiration, 44; temperature, 98 $\frac{3}{4}$ °. Breathing more through the nose and mouth than through the opening; bowels moved; drank one pint and a half of milk, half an ounce of wine, cup of tea; discontinued the steam from the slacked lime, kept the air in the room moist by steam from the spout of a boiling tea-kettle. 10 P.M. Pulse, 112; respiration, 32; temperature, 98 $\frac{1}{2}$ °. Eaten some beefsteak, a piece of lemon pie, drank a quart of milk, cup of tea, one pint and a half of wine; is dressed and playing about the room; opening in trachea closing rapidly. Quinia sulph. gr. iv.

14th, Pulse, 120; respiration, 32; temperature, 98 $\frac{3}{4}$ °. Breathing entirely through the mouth and nose; child coughs occasionally, when a little air escapes through the wound; bowels moved; taken one pint of milk, an ounce of wine, a squab, and a piece of toast; ordered an emulsion of cod-liver oil and phosphate of lime three times a day.

From this time forward she improved rapidly; the wound in the trachea healed nicely; the voice returned, and in a few days she was playing about as usual. Continued the cod-liver oil for several weeks.

In conclusion, I would state, recovery was in a very great measure due to the fact that the air was kept constantly moist by slacking lime, and to the frequent inhalation of warm vapor from sponges squeezed out in hot water and salt, which afforded the only relief when the dyspnoea was greatest, softened the mucus and facilitated the separation of the diphtheritic membrane.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES OF TREATMENT.

TYPHOID FEVER—ANTIPYRETIC TREATMENT BY MEANS OF COLD BATHS.

THE two cases here recited were such as demanded the use of the cold bath, and the measure was followed by excellent results.

The first patient was aged 28, and when admitted her pulse was 132, respiration 42, and temperature 105° F. Her tongue was dry; lips and teeth covered with sordes; she was quite deaf; her face had a dusky color; and she could be roused only with considerable difficulty.

Oct. 24.—Morning temp. 104 $\frac{1}{2}$ ° F. Evening, 105° F.

Oct. 25. " " 103 $\frac{3}{8}$ ° F. " 104 $\frac{7}{8}$ ° F.

The effect produced upon the system by the disease seemed to be rapidly increasing.

Oct. 26.—To-day the baths were commenced, and the first was given at 5.30 A.M.; having a temperature of 80° F., was continued ten minutes, and brought the temperature of the patient down from 104 $\frac{7}{8}$ ° F. to 102 $\frac{1}{4}$ ° F. At 8 A.M. the temperature began to rise, and the bath was repeated with the result of bringing the body

heat down from 103 $\frac{1}{2}$ ° F. to 99° F. in the axilla, and to 102° F. in the vagina. The vaginal temperature only will now be recorded.

Oct. 27.—Morning temperature 103 $\frac{1}{4}$ ° F. Evening, 103 $\frac{3}{4}$ ° F. During the morning hours the patient received three baths, and the temperature was made to remain at about 101 $\frac{1}{4}$ ° F. In the evening it arose to 104° F., and the bath was repeated with the result of bringing the temperature down to 101° F.

Since Oct. 27th, it has not been necessary to repeat the baths, the temperature not rising above 103° F. in the evening, and at date (Nov. 8th), the patient had a morning temperature of 99 $\frac{1}{4}$ ° F., notwithstanding the fact that her case had been complicated with hemorrhage from the bowels.

The second patient was admitted Nov. 1st. On Nov. 3d the temperature was 103 $\frac{1}{2}$ ° F. in the morning; her tongue was dry and brown, and there was marked tremor of the muscles. In the morning the temperature had risen to 106 $\frac{1}{4}$ ° F. in the vagina. The cold bath was used of the same temperature and duration as in the first case, and half an hour afterwards the temperature was 103 $\frac{1}{2}$ ° F. The effect of this bath continued until the next morning, when the temperature again began to rise, and the bath was repeated, with the same happy effect. Three or four baths were given daily, and the usual hours for their use were four, six, and eight in the afternoon. Several times the temperature had remained at a comparatively low degree as long as twelve hours after receiving a bath, but had risen again as high as 105° F., or more, in the evening. The prognosis in this case, notwithstanding the good effect of the cold bathing, was rendered quite unfavorable by the fact that the patient had been a very intemperate person previous to the attack of fever.

TYPHOID FEVER—QUININE AS AN ANTIPYRETIC.

THIS case of typhoid fever was characterized by rather an unusual intensity of temperature. The only agent used to control it, was the sulphate of quinine, and with what result can be seen below. The quinine was administered in solution with dilute sulphuric acid.

A male patient, *æt.* 22, a sailor, came direct from the ship to the hospital, and was admitted Oct. 20th, 1875. He had been sick six days before admission. When admitted he received grs. xx. of quinine. The following morning his temperature was 104 $\frac{1}{4}$ ° F. in the axilla, and grs. xx. of quinine were administered. One hour after, the axillary temperature was 104 $\frac{3}{4}$ ° F., and the rectal 105 $\frac{1}{2}$ ° F. The average difference between the axillary and rectal temperature has been about 1° F., and hereafter only the rectal will be given. Through the day (Oct. 21), from 10 A.M. until 7 P.M., his temperature ranged from 105° F. to 106 $\frac{1}{4}$ ° F., and back to 105° F. At 7 P.M. he received grs. xx. of quinine.

Oct. 22, 12.30 A.M.—Temperature, 102 $\frac{3}{4}$ ° F.; at noon, 105 $\frac{1}{2}$ ° F.; at 5 P.M., 105 $\frac{1}{4}$ ° F.; and within this time grs. xl. of quinine had been taken.

 12 NOON, " $104\frac{1}{2}^{\circ}$ F.; grs. xx. quinine.
 2 P.M., " $103\frac{3}{4}^{\circ}$ F.
 4 " " $103\frac{1}{2}^{\circ}$ F.

Such was the antipyretic treatment up to date (Oct. 28), and notwithstanding this and the natural effects of his disease, he was exceedingly comfortable, and the morning of Oct. 28th had a pulse of 77, respiration 21, and a temperature $103\frac{1}{2}^{\circ}$ F. The eruption was well marked; diarrhoea slight; tympanites almost nothing; tenderness in the right iliac fossa slight; and the man evidently was not suffering from severe constitutional disturbance. The tongue was a trifle tremulous, but moist; no accumulation of sordes, and no delirium.

Thermometrical record of the case continued.

Oct. 28th, 8 A.M., T. $104\frac{3}{4}^{\circ}$ F.
 12 NOON, " $104\frac{3}{4}^{\circ}$ F.
 2 P.M., " $105\frac{1}{2}^{\circ}$ F.; grs. xx. quinine.

 8 " " $103\frac{3}{8}^{\circ}$ F.
 Nov. 3d, 8 A.M., " $102\frac{1}{2}^{\circ}$ F.
 10.30 " $102\frac{3}{4}^{\circ}$ F.
 12 NOON, " $103\frac{1}{2}^{\circ}$ F.
 2 P.M., " $104\frac{3}{8}^{\circ}$ F.; grs. xxx. quinine.
 4 " " $104\frac{3}{4}^{\circ}$ F.; grs. xxx. quinine.
 6 " " $103\frac{3}{4}^{\circ}$ F.
 8 " " 102° F.

The symptoms in this case since the 28th had not been severe, except the temperature, if that can be called severe when all the rest are mild. There had been no delirium, and the general appearance of the patient throughout the course had been good.

Progress of Medical Science.

ON FISSURE OF THE NECK OF THE BLADDER AND RAPID DILATATION OF THE URETHRA IN WOMEN.—Prof. Spiegelberg, of Breslau, insists upon the advantages of rapid dilatation of the female urethra, for purposes of accurate diagnosis and radical cure of various affections of that region. He claims that the inflammation of the mucous membrane and the incontinence of urine, which have been found so troublesome after gradual dilatation, are avoided in this mode of treatment. The dilatation can be carried up to almost an inch without risk; but it should be practised under chloroform, because of the pain it occasions and to avoid injury from sudden movements of the patient. The process occupies about a minute, the urethra being first moderately and then vigorously stretched. He uses Busch's uterine dilator, removing the upper branch, while for mere inspection Simon's specula will suffice. He has successfully employed this method in treating a polypus of the neck of the bladder, and even in evacuating the fluid in a case of hæmatometra, but regards it as specially applicable to the treatment of fissure of the neck of the bladder, of which he reports two cases successfully treated. This affection he regards as wholly analogous to fissure of the anus, both often following confinement, involving annular muscles, and requiring the same treatment. The pain and spasmodic contractions are more constant in vesical than in anal fissure, because the urine as it accumulates comes at once into contact with the raw surface, while there is always an interval before the feces reach the sphincter in their descent. As a method of diagnosis this obviates the danger of mistaking the affection in question for a cystitis, a urethritis, or a simple neurosis.—*Berl. klin. Woch.*, XII, 16, 1875.—*Schmidt's Jahrb.*, Sept. 7, 1875.

THE COLORING MATTER IN TRAUMATIC ICTERUS.—According to M. Poncet, traumatic icterus is due to the resorption of the coloring matter of the blood. The coloring matter is, in this case, modified or reduced hæmoglobine, that is, hæmoglobine deprived of its oxygen. The spectral analysis of an ecchymotic liquid shows a peculiar characteristic band of reduced hæmoglobine. This liquid, treated with ether, gives a yellow coloring matter, which is separated from the hæmoglobine, and is the same that gives to the integument its icteric tint.—*Gazette Médicale*, Sept. 25, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, December 18, 1875.

DIPHThERIA AND FILTH.

THERE seems to be a growing impression that many of our epidemic diseases may originate in *filth*, a term which is applicable not merely to foul organic matter in solid masses, but also to minute portions of it suspended in water or in the air. One or more of these conditions appears to call out typhoid fever or diarrhoeal diseases, and this relation has been so marked in many cases that filth has come to be regarded by some as the actual cause of their occurrence.

Whether or not this is true, and whether or not we have found the specific poison in such instances, does not appear to have so much practical importance as the fact that we know the chief agencies by which infection is produced, and so may plan means to counteract them.

Acting upon the basis of these views, we should expect that approved sanitary measures would greatly mitigate the force of these diseases, and, in fact, this has really been accomplished, as shown by the statistical returns from villages and towns where sanitary regulations have been vigorously enforced.

The English reports are particularly valuable for the illustrations they afford of the working of these sanitary systems, especially in reference to typhoid fever and diarrhoeal diseases. But while the attention of sanitary men has been so closely engaged in this especial direction, it can hardly be supposed that the element of filth may not also influence the occurrence of other affections. Indeed, these same reports tell us that outbreaks of both diphtheria and scarlet fever were closely associated with filth-nuisances of some sort or other. The evidence, however, is not altogether complete, for the instances of this kind are comparatively few, and, indeed, they are so far adverse to the filth theory, that the introduction of sanitary reforms was not followed by any uniform diminution in the mortality from these sources.

It is, however, to be said, that statistics of diphtheria are liable to peculiar sources of error. In the first place, the name itself is a comparatively new one, not having appeared on the English registers before 1856, while in this city the occurrence of the first case is well remembered by some of our older physicians, though at the same time we have no good reason to suppose that the disease is a new one. Then, again, there has always been a division of opinion among the best practitioners as to the precise elements in a differential diagnosis of diphtheria, which, it is well known, in the milder forms presents uncommon difficulties. These facts will serve to explain why too much reliance should not be placed upon statistics gathered from a wide range of inquiry. The careful investigation of an outbreak in a single town, where the cases have been known to an intelligent physician, are of much more value. In this connection our readers will have noted that the last number of this journal contained an article bearing certain considerations on the origin of diphtheria. The writer has made an impartial selection of twenty houses where the disease had appeared in a single town, and he has directed his inquiries towards the condition of the cellars and underlying soil. All of the inspected houses were built on an alluvial formation, the cellars were generally damp or wet, and in all cases insufficiently ventilated. The greatest fatality occurred in those that were built upon filled land, where the subsoil was clay and the cellars were wet. In such cases the exhalations of the ground were naturally laden with the products of decomposition, and being undisturbed by currents of air, and in the presence of a moist atmosphere and mild temperature were, in the writer's opinion, "accessory to, if not productive of, zymotic poisoning." The direction which these investigations took is interesting, and they point to results of practical importance.

In this city diphtheria seems to have been greatly influenced by conditions of a somewhat similar nature. In a large number of cases the possibility of infection from person to person has been almost inconceivable, especially when the poison seems to have such a limited capacity for transportation. Careful inspection of the premises in such cases has shown that sewer-gas could enter the apartments, either through defective drains, leaky pipes, or deficient traps; perhaps there was a lack of water to flush the basins or sinks, or foul matter had been allowed to collect on the premises or in the immediate neighborhood. These or other unsanitary conditions have almost invariably been found to be in operation when isolated cases have been investigated. Sometimes the filth nuisances were so plainly apparent that even non-professional persons believed them to have generated the sickness. These facts, of course, may not militate against the view that the poison has also a capacity for conveyance, of which many excellent examples are

given. And yet, if the filth origin of diphtheria be admissible, it is then easy to conceive how many persons in one house may take the disease, not from each other, but from the same foul source.

But while we are able so often to associate gross sanitary neglects with the origin of diphtheria, we must be alive to the fact that a hardly less censurable condition of things is often present in houses where we should least suspect it. Filth is not merely the companion of the poor and uncivilized. Indeed, so far from this being the case, many of the poorest families in the city observe rigid cleanliness in their homes, though the buildings they live in be pest-houses. The fault may be with their landlord, who perhaps has given them leaky pipes, a scanty supply of water for their basins or sinks, improper water-closets, or has allowed the cellars or yards to be receptacles for all manner of foulness. Nor is it these landlords only, but the masters of substantial and elegant residences in the better portions of our city, who either from indifference or ignorance of the commonest sanitary rules, leave the doors wide open for the entrance of disease. Privies that are used by their subordinates are allowed to get out of repair, and are then heedlessly used until the nuisance become so excessive that the evil betrays itself.

Ashes and garbage also are sometimes allowed to collect in the areas or basements, until it suits the convenience of the servants or masters to have them removed. Nor is it very uncommon for the better class of houses to have worn out soil-pipes, which breathe out pestilence whenever there is pressure of sewer-gas. The common lead soil-pipes, with which so many of our houses are fitted, is now known to last but a comparatively short time. Under the influence of sewer-gas alone there is a gradual corrosion of the lead, and this action appears to be rapid or slow according to the amount of pressure. When such pipes are removed they are often so thin that a pin can be pushed through them, and even have large holes at the bends. These pipes are often hid away in the walls, and their condition is not known until a serious break has taken place, but meantime they have been pouring out their noisome vapors into the house. Nor is this all, for there are those living among us in good circumstances who altogether abuse the advantage which a good water system has given us. Such persons would scorn to be accused of anything uncleanly, but at the same time will sometimes not hesitate to use water-closets when out of order, and often fail to properly flush them sufficiently to carry off the waste beyond the trap, even when the water supply is abundant. When such water-closets are in the vicinity of sleeping rooms, and have imperfect communication with the outside air, the evil becomes an intolerable nuisance.

It is these dangers, together with the difficulty of at all times keeping back the sewer-gas from houses, that has led to a common notion that water-closets

and wash sinks and basins are so detrimental in their operation that the safest plan is to remove them as far as possible from dwelling-houses, or at least to reduce them to a minimum, and return to the old pitcher-and-basin system. This, however, appears to be carrying the matter to extremes. Authorities appear to be agreed that for our cities at any rate the water system offers the best advantages, and is the most effective way of removing waste.

Another possible source of danger is our drinking water. As it comes to us through our direct pipes it is pretty sure to be sound and healthy, both because it comes to us from a comparatively pure source and it is robbed of its organic particles during its passage down. But we are apt to forget that in our own houses the water may be contaminated in various ways. One of the most common is for the overflow pipe from the tank to communicate with the sewer pipe, so that thus the sewer gas is led directly to the water supply.

A soil drenched with organic matter is also capable of giving out noxious gases, as pointed out by our recent contributor, and it is in such neighborhoods that diphtheria has shown a tendency to prevail—parts where there is neither sewerage nor drainage, and where the waste can collect in pockets on the surface or soak away into a spongy soil.

Many persons do not appear to be aware that these sanitary abuses are constantly in existence about us, but they are matters to which public attention should be turned, that they may be the sooner abated.

THE LOCALITIES OF MALARIA IN THE CITY.

THE Health Board is endeavoring to ascertain the different localities on the built-up portions of this city subject to strictly malarial troubles. Not only is this inquiry to be confined to intermittent and remittent fevers, but to all the obscurer diseases in which the element of periodicity is sufficiently well marked to cause suspicion. A map of the city is sent to each physician, with the request that he will indicate the precise situation of each case of the sort which he may be called upon to treat, and transmit in due time the results of his labors. This is a matter of the greatest possible importance in connection with the true sanitary interests of the city, and it is to be hoped that every medical man will do his utmost to second the endeavors of the Board and offer to it any suggestions which may tend to promote the end in view. It is by the accumulation of such reports that a scientific basis can be made for an accurate estimate of the means which may be necessary to remedy the evil.

MEDICAL NIGHT SERVICE.

WITHIN the past few days a physician of New Brunswick, New Jersey, was called at night to see a patient in the suburbs, and was not again seen alive. The par-

ticular locality in question is notoriously disreputable, and there is good reason for supposing that his messenger deceived him thither for purposes of foul play. The body of the unfortunate physician was subsequently found in the canal with his pockets rifled, while his empty wallet and cravat were discovered on the bank. The possibility of suicide is entertained, and this theory of the cause of his untimely end may be substantiated; but in any event the case will have a tendency to impress upon the mind of every one who is liable to chance calls at night the necessity of guarding against a possible danger. We have always congratulated ourselves that the very calling of a physician granted him an immunity from such perils; but that we must disabuse ourselves of this idea is quite apparent from several murders of physicians under like circumstances which have recently come to our notice. If similar occurrences multiply themselves it may be exceedingly difficult to obtain night help even for those entitled to it. A physician is ever ready to render service to the needy, and for this purpose never shrinks exposure to the inclemency of the weather nor hesitates to sacrifice his hours of repose, but it can hardly be expected that he will add to all this the risk of being the prey of the midnight assassin.

HOSPITAL APPOINTMENTS.

THE remarks on hospital appointments by one of our correspondents deserve a great deal of attention on behalf of the large number of medical men who are interested in the discussion. The evils of which he complains are matters of fact, and the remedies which he proposes are deserving of thoughtful consideration. We are not very sanguine, however, that either of the plans which he suggests can be turned to practical account. Continuous medical service in our hospitals is very desirable on many accounts; but our clinical teachers, working as they do for the colleges, have no great incentive for work when there are no students in town, neither is there any question in regard to the utility of competitive examinations; but the opposing element in the shape of men who already hold hospital appointments, or who expect to gain them by influence rather than real merit, is still strong enough to render the immediate adoption of his plan hardly possible. We wish, however, it were otherwise, and still hope for the best.

THE KANGAROO is said to have become acclimated in France, where several landed proprietors have introduced them to their own grounds, where they are hunted like other game. The flesh is now sold in the markets as an article of food, and is considered a great delicacy.

DR. LOMBE ATHILL has been appointed Master of the Rotunda Lying-in Hospital, in Dublin, *vice* Dr. George Johnson, whose term of office has expired. The other candidate for the position was Dr. Cronyn.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 2, 1875.

DR. S. S. PURPLE, PRESIDENT, IN THE CHAIR.

FUNCTIONAL DISORDERS OF THE HEART CHARACTERIZED BY NOTABLE INFREQUENCY OF THE PULSE.

AFTER the transaction of important routine business referring to nominations, Prof. Austin Flint, Sr., read a brief but interesting contribution, in which he set forth the statement that functional disorder of the heart, seen in the forms with which every practitioner is familiar, is characterized by paroxysms of violent and fluttering, or irregular or intermittent action; the patient is distressingly conscious of disturbance about the heart, with a dread of sudden death; the paroxysms, sometimes momentary, sometimes lasting for hours, occurring at longer or shorter intervals; occurring especially during the night; occurring often without obvious exciting cause; but in the main dependent upon mental depression, derangement of digestion, venereal excess, tobacco, mental excitement, mind filled with apprehension of heart disease, leading the patient to watch his or her own heart with the greatest care, feeling its beats, noticing its irregularities and its intermission, etc.

INCREASED FREQUENCY OF PULSE.

An infrequent variety of functional disorder of the heart is characterized by a persistently rapid pulse without disturbed rhythm of the heart's action. This is a marked feature of Graves' disease, or exophthalmic goitre. The rhythm of the heart's action is usually regular, but the frequency of the pulse may be persistent for months and years. The disorder in this disease is doubtless functional, for the reason that there are no physical signs of organic disease of the heart necessarily present. Before determining whether this variety of functional disorder is present or not, it must be determined whether the same persons have naturally a notably frequent pulse, and without noting this peculiarity a needless distress may be caused. In this connection a case was related in which the pulse was never below 100, and a considerable portion of the time reached 120, and yet the lady was not aware of being in ill-health. This case was brought forward as an example of frequent pulse as a normal peculiarity. If otherwise, it showed that a frequent pulse may be continued for a long time without giving rise to any particular trouble. The case was under observation a number of years, and there were no physical signs of affection of the heart.

INFREQUENCY OF THE PULSE.

Functional disorder of the heart, characterized by a notable infrequency of the pulse, is a variety which is much more likely to occur than that to which reference has just been made. If it is not a variety, but is a distinct form of disorder, then there has heretofore been a hiatus in our study and knowledge of cardiac diseases. The histories of five cases were submitted as a simple contribution to the literature of the subject, and with the belief that they go far towards substantiating the fact that there is a variety of functional disorder of the heart characterized by a notable infrequency of the pulse. One case was alluded to, before proceeding to his own, that has already been reported by Mr.

Thornton in the eighth volume of *Clinical Transactions*, published in London, August, 1875. The patient was a woman *æt.* 20, married, anæmic and thin. She entered the service to obtain relief from a syphilitic laryngitis. Her pulse was 40 to the minute. The emergencies of the case demanded the operation of laryngotomy. Her pulse remained the same after as before the operation. Not long after, the pulse lowered in frequency to 16 to the minute, the patient at that time suffering from transient attacks of giddiness. There was no evidence of organic disease of the heart, and the pulse gradually increased in frequency until it reached 40, and subsequently, when the patient was in a state of apparent health, it numbered 48. The patient had an epileptic seizure before the operation, and several afterwards. In the intervals between the convulsions the pulse usually numbered 24, and during the epileptic seizure complete intermissions, 16 and 18 seconds in length, were noticed.

The Professor's *first* case was a patient, about 35 years of age, the wife of a medical gentleman, who came under observation some seven or eight years ago, and at that time was full of apprehension that she had disease of the heart. Repeated physical examinations were made, but always with negative results. While at dinner one day a morsel of food disturbed the larynx, in such a manner as to give rise to a fit of coughing, a sense of suffocation and vomiting. The patient became livid in the face, and there was very great prostration. She fainted the moment her head was raised. Her pulse numbered 40 to the minute, and during her illness there was no evidence of cardiac disease. Several years subsequently the patient died of typhoid fever, and post-mortem revealed the fact that no cardiac lesion was present.

The *second* case was a person, *æt.* 38, and a convalescent from acute pneumouia affecting the right lung. The physical signs of the pneumonia had nearly all disappeared when the patient was seized with a sense of great prostration, a feeling as though death was impending, was covered with cold perspiration, and had a pulse of 40, and markedly intermittent. There were no cardiac murmurs audible, nor was there any increased area of cardiac dulness. The patient was of a highly excitable temperament. These attacks continued to recur for about six weeks, and were sometimes repeated as often as three times a day. But they finally ceased entirely, and complete recovery took place. At no time was there any elevation of temperature, and the examination of the urine gave only negative results. The lowest number reached by the pulse was 35. Brandy and ammonia were administered without effect upon the pulse, but usually calmed the excitement of the patient.

The *third* case was communicated to him, and occurred in a patient, *æt.* 53, previously healthy, who, after some exposure, had a feeling as though a cold had been contracted, whereupon he took a foot-bath, a hot punch, and retired early. The following day he indulged in the sport of a fox-chase, upon horseback. His appetite was moderately good, he slept well, had no cough, no sore throat, and suffered only from a sense of weakness through the upper portion of the trunk. His pulse numbered 26 to the minute; rhythm, fulness, and force good. Respiration 24. The heart was of normal size; sounds distinct, and impulse natural. The bowels were regular, urine abundant, with *sp. g.* of 1010. Urinary analysis negative. The patient was obliged to maintain the recumbent position. In the evening five grains of quinine and five grains of calomel were given, and repeated

until four doses were taken. On the morning of the second day the respirations were 14; a single discharge from the bowels had occurred, and the pulse had increased to 32. On the third day the pulse was 36, and the cathartic, which had been repeated, had acted quite freely. On the fourth day the pulse was 42; on the fifth, 60; on the sixth, 80; and the patient then resumed his work.

The *fourth* case was seen in consultation. The patient, *æt.* 46, had been robust, except that he had suffered considerably from malarial fever, and at the time he was seen in consultation cephalalgia was the prominent symptom, and more severe at night. There was some evidence of delirium present. The pain in the head was persistent, and was finally relieved by morphine. In this case slowness of the pulse was a notable feature. In health the pulse of the patient ranged from 70 to 75. About ten days after the date of the commencement of the illness it numbered 40, once only 38, and increased in the evening to 46 or 48. The patient made a complete recovery. The slowness of the pulse continued for some time, but it gradually became more frequent, and finally reached 74.

The *fifth* case was seen in consultation, in January, 1874. The patient, *æt.* 43, had suffered from habitual constipation, but aside from that had been in fair health. He began to suffer from a sense of weakness and palpitation, and the pulse numbered 40. There were no abnormal cardiac sounds; lungs were healthy; urine normal; liver and spleen not enlarged, but there was some vertigo. In April his pulse ranged from 30 to 34, and in May from 30 to 40. In May, 1875, he had an epileptiform seizure, which was attended by copious vomiting, and the seizure was repeated within the month. His pulse was from 24 to 36 during the interval between the seizures. From May to August he had slight attacks, and the pulse was 36, and irregular. Digestion poor.

August 3, 1875, he had an epileptic seizure, and during the convulsion his pulse was 40, but returned again to 26. In September his retinae were examined, and found normal. Phosphorus was now introduced, nearly the entire materia medica having preceded it, and the pulse increased from 26 to 36. In November, 1875, the patient was about, but there was a marked tendency to faintness. Urine normal. No record of pulse before the present sickness. But assuming the normal rate to be 80, a reduction to 26 is sufficiently remarkable to make the case worthy of note. At date the pulse was 36; rhythm regular; no murmurs; no cardiac hypertrophy.

Of these cases four were males and two females. They were aged respectively 20, 35, 38, 53, 46, and 43 years.

The lowest pulse reached in each case was respectively 16, 40, 35, 26, 38, and 24.

In each case recovery took place except the last, who is still under observation. In all the cases in which complete recovery was seen the pulse returned to its normal rate, except in the *second* case, where it remained at 48. It is questionable whether 48 was not the normal rate in that case, but it is altogether probable, however, that the patient would have been cognizant of the peculiarity had such been the fact. That a persistent infrequency of the pulse may be acquired without any impairment of the health, is probably true.

As an acquired normal peculiarity, however, it is rare. Infrequency of the pulse, denoting a variety of functional disorders of the heart, seems to be associated with marked cerebral disturbance.

This was true of all the cases reported, except one.

DIAGNOSIS.

The diagnosis involves, *first*, determining whether the infrequency is not a normal condition, either congenital or acquired. The pulse of Napoleon the First was said to be only 40, normally. As a rule, it may be safely assumed that, if the patient is ignorant of such a peculiarity, it is not normal. Organic affections of the heart are to be carefully excluded.

There is a condition of regular irregularity of the heart's action which must be excluded. That is, there is a condition in which the radial pulse indicates just half the number of heart-beats. The carotid pulse will enable us to exclude that condition. Cerebral hemorrhage, thrombosis, jaundice, uremia, are all easily excluded. Subacute or chronic meningitis may not be excluded with so much ease in some cases, but the cerebral symptoms indicative of compression of the brain are usually sufficient to differentiate meningitis from functional disorder of the heart, with slow pulse. Not every case, however, of meningitis presents these symptoms. Infrequency of pulse produced by drugs can also be easily excluded.

PATHOLOGY.

Physiology has demonstrated that the frequency and force of the heart's action is regulated by the constant nervous influence transmitted to the fibres of the pneumogastric nerves, which are distributed to that organ. It is apparent that in the ordinary forms of functional disorder, those which are characterized by an increase in the frequency of the pulse, there is a diminished influence, or a paralysis of the nerve-fibres.

But an infrequent pulse involves an abnormal increase of the resisting or inhibitory influence which is exerted through these nerves.

Why this influence is exerted we do not know.

PROGNOSIS.

Prognosis is favorable. There is no evidence that the inhibitory influence can be affected to such an extent as to endanger the life of the patient.

TREATMENT.

A purge in one of the cases was demonstrated to be of importance. Strychnia, atropia, iron, and subsequently phosphorus, were followed by partial relief in one case. What is desired is a remedy which will have a direct effect upon the inhibitory function of the pneumogastric nerves, and restore it to its normal relation. Theoretically, opium was suggested as being likely to prove useful. It should be given in *continuous* doses; that is, in such doses, and repeated at such intervals, that the influence of the drug will be continuous.

Perhaps this notable infrequency of the pulse is not so rare as is supposed, and further, perhaps not a few of those who have heard the paper may be able to recall a case or cases which have been under their observation.

Dr. F. N. OTIS reported a case coming under this head, which occurred in a young man, *æt.* 28 or 30, who was suffering from an attack of acute epididymitis. The doctor's attention was drawn to the pulse, which was found to be only 46 or 48. At the same time the patient had profuse perspiration, coming on without apparent cause, and several such attacks would occur within twenty-four hours.

In other respects he was apparently well, except the epididymitis. There was no febrile movement, no pain, no cachæ lesions; but the patient was quite nervous. The pulse remained in this condition about three days; perspiration profuse, especially at night.

Whether the quinine and iron which were administered had anything to do with the recovery, he was uncertain. The pulse returned to 74.

Another case was mentioned, in which the pulse was reduced to 46, apparently by the influence of chlorate of potash, for it at once recovered its normal frequency when the drug was discontinued.

Dr. BLUMENTHAL referred to four cases of this character which he had seen. As a rule, he thought this condition of pulse was the precursor of some serious trouble. In one of his cases the patient had a pulse of 40 for a few weeks, and then suffered from a distressing carbuncle. He regarded the slowness of the pulse as symptomatic of impending serious disease.

Dr. L. D. BULKLEY referred to marked fluctuations in the number of the pulse-beat, and out of 250 cases five were recorded among the fifties. In one case there was a variation of 46 beats in 17 days; not from febrile action before or during the skin disease, which gave rise to the variation in the pulse.

Prof. E. R. PEASLEE mentioned two cases as bearing upon a single cause for slow pulse. The first was a man, *æt.* 62, in whom the pulse became reduced to 38, and continued so for about one month. The second was a man about 45 years of age, always perfectly healthy, in whom the pulse numbered 40. In both cases it was due to the use of tobacco, and when that narcotic was excluded the pulse returned to the normal standard. He also alluded to the fact that during the war, while examining about 450 men over 18 and under 45, he found the pulse at 40 or 50 in a certain class of men, namely, cigar-makers. He farther experimented with them, and found that when it was announced to them that they must go to the war the pulse would rise at once, but would soon return to the low rate. He regarded the slow pulse as being due to some effect produced by the tobacco upon the inhibitory influence exerted by the pneumogastric nerve.

Other narcotics perhaps may produce the same effect.

Prof. JACOBI alluded to paralysis of the sympathetic as producing a slowing of the pulse. Perhaps a few of those cases mentioned by Dr. Flint can be explained in that way. Some of them evidently belonged to the neurotic class of persons. Now we know that in neurotic persons a hemierania, for instance, may occur dependent upon a spastic or paralytic condition of the vaso-motor nerves. He had observed slow pulse, especially in little girls, sometimes irregular, and had been fearful of a termination in basilar meningitis, but was disappointed by finding that the pulse went up again as the general condition of the patient was improved.

A number of causes resulting in general anæmia will produce infrequency of the pulse. On the other hand, anæmia as a rule produces a frequent small pulse. His conclusion was that functional infrequency of the pulse may be explained in different ways in different cases. Either we have to deal with debility of the heart muscle, or we may have to deal with irritation of the pneumogastric nerve, or we may have to deal with paralysis of the sympathetic.

Changes in the circulation will follow the latter, such as attend dilatation of the blood-vessels. This condition may be benefited by remedies which act directly upon vaso-motor nerves. Quinine will benefit by giving tone to the blood-vessels. Atropia, or belladonna, will probably benefit the condition of the sympathetic.

On the other hand, we may have a change in the

sympathetic ganglia substance which will give an infrequent pulse.

The Academy then adjourned.

NEW YORK MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

Stated Meeting, Dec. 3, 1875.

DR. E. R. PEASLEE, PRESIDENT, IN THE CHAIR.

CASES OF DIPHTHERIA.

THE evening was devoted to the relation of cases, of which the following were the more important:

DR. JOEL FOSTER referred to four cases of diphtheria lately under his care. There was nothing peculiar in the first case, except that the disease first attacked the nostril, which remained impervious for ten days. The exudation extended to the posterior nares and fauces.

Local Treatment.—Weak solution of carbolic acid injected into the nostril three or four times a day. The throat was penciled twice a day with a mixture consisting of

℞ Liq. ferri persulphatis. ℥i.
Glycerine. ℥ij.
M.

This mixture did not irritate, and the doctor believed it to be beneficial.

Constitutional Treatment.—The child was ordered teaspoonful doses of the following mixture, and the most sustaining diet:

℞ Quin. sulph. ℥i.
Tr. ferri muriat. ℥i.
Syr. tolu. ℥ijss.
M.

S. Teaspoonful four times a day.

The patient recovered. The doctor made the most careful exploration of the house and premises, but was not able to find any local cause. An attempt was made to quarantine the other children in the family, but the effort failed and another child was attacked. The disease in that case appeared first in the fauces. Treatment as above, and recovery followed. In each of these cases during the first few days there was considerable febrile action, and the patients were partially delirious.

The third case occurred in a girl, *æt.* seven years, who took the disease at school. It appeared first in the fauces, and was relieved by the local and general treatment mentioned, when all at once she gave alarming symptoms, indicating an invasion of the larynx.

Four mornings in succession the local mixture was applied to the larynx by means of a curved probang and sponge, and three times pieces of membrane were brought away. No membrane following the sponge the fourth time, it was discontinued. Everything possible was done to nourish the patient and sustain her strength, and a chief reliance made upon steam as a local measure for removing the membrane. A flexible tube, twelve feet long, was attached to the spout of the tea-kettle, whose cover had been sealed by means of india-rubber strips. The length of the tube permitted the steam to be cooled sufficiently, so that the patient was able to breathe it almost continuously. This inhalation was maintained *twelve* days, and at the end of that time all alarming symptoms had passed. At present there is complete loss of voice, but the patient is doing well.

The fourth case, a little girl *æt.* four years, had

a profuse epistaxis on the third day, which resisted repeated attempts to arrest it, and she succumbed to the disease and the effect produced by the hemorrhage.

DR. BURRALL directed attention to thorough sanitary regulations as bearing upon the great prevalence of sore throat in certain localities in this city, especially along the line of old watercourses.

DR. PEASLEE mentioned an instance as related to him, where a boy was attacked with diphtheria while at school, and *thirteen* students who attended school in the same room were also attacked, and six died. In the adjoining room, however, also occupied for school purposes, not a single case occurred. In such an instance it would seem as though there was some local cause, which suggests that there should be the most careful inspection of the premises when the disease makes its appearance.

DIAGNOSIS OF PUERPERAL INSANITY.

DR. BURRALL spoke of the difficulty in determining, in certain cases of pregnancy, whether the woman is in the commencing stages of insanity, or whether her actions are actually dependent upon a bad temper. Every practitioner must be more or less familiar with such cases.

DR. JOEL FOSTER regarded that peculiar crossness, irritability, a sort of ability to raise the (his satanic majesty) upon the least provocation, and sometimes without provocation, as a very common condition among pregnant women.

DR. PEASLEE remarked that it was one of the perplexing questions to decide, whether there is foundation for such actions on the part of pregnant women in the peculiar condition incident to pregnancy, or whether they are due to sheer ugliness; for a woman may have puerperal mania before confinement as well as subsequent to parturition. In this condition she will manifest the greatest hatred to those whom she loves the best, and will perpetrate the greatest meanesses. Yet there are cases where it would seem as though the demonstrations of these women were made up of one-eighth hysteria, one-eighth insanity, and three-fourths deviltry. There is an evident pleasure in annoying those whom they should love the best, and they will sometimes indulge in attacks of personal abuse, striking and kicking in a manner that is not easily explained upon any other ground. It is, perhaps, difficult to say whether it should be called insanity or not; but he was quite of the opinion that deviltry is at the bottom of a good share of the demonstration, and in any event that little sympathy and much discipline is the best thing that can be done for the woman. She should be brought to terms by all concerned.

DR. LUDLUM mentioned a case of facial erysipelas, which was interesting to him from the fact that the nose was swollen for several hours before the erysipelatous blush made its appearance.

He also mentioned a case where a prisoner succeeded, by introducing tobacco into the rectum and wearing a pad in the axilla, in producing slowness of the pulse sufficiently marked to enable him to escape from performing the hard labor to which he had been sentenced.

He also referred to the removal of foreign bodies from the ear, and insisted that they should never be removed by anything except a stream of water from a syringe. The reason for so doing lay in the liability to produce injury to the auditory canal by any other method.

(To be continued.)

Correspondence.

HOSPITAL APPOINTMENTS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—Your remarks upon our system of hospital appointments are very timely, and as the sole hope of a change in it lies in the formation of a public, or rather a professional opinion which will render the continuation of the present condition impossible, I venture to give a push to the ball you have started.

But it is not the mode of appointments alone I would arraign. That is but a part of a faulty whole, and I propose to show that our hospitals are far from doing what they should, either for the physicians, students, or patients, and that these defects can be remedied by a change in their management.

In my judgment, the most efficient cause of these evils is the system of service. Each physician goes on duty for two or three months only, and during his term of service visits his wards twice or at most three times a week. He comes whenever he finds it most convenient, meets his "House," asks what patients the latter would like to have him see, visits those and the few others in whom he has some especial interest, and goes away after having seen not more than a quarter of those confided to his care. If he is a young surgeon he performs most of the operations, but as he advances in years and experience he leaves much of this work to his assistants, and contents himself with the rôle of "counselor and friend." This lack of interest is not entirely his fault. His wards are large, his term of service short, the history of his patients utterly unknown to him when he goes on duty, and their treatment under his control only for what is in most cases an inadequate length of time.

What is the effect of this upon the patients, the house staff, and the physician himself? The patients are to all intents treated by the internes. A general line of treatment may be suggested by the visiting physician, but all the details and modifications are attended to by the former. In short, the patient is treated, and in many cases operated upon, by a young gentleman who is undoubtedly intelligent, but whose knowledge is limited to what he can assimilate from his text-books and to twelve months' at most, sometimes only six months' hospital experience in a subordinate position. If under these circumstances the patient is as well cared for as he would be if seen daily by the visiting physician, it can only be because years and experience bring no profit, and the average graduate is as good as the average practitioner.

Now, as to the resident staff. Twice a year each hospital turns out half a dozen young men, each of whom has had in it on an average a year's experience as assistant, and six months as "House." During the latter, he has had almost the sole charge of from 100 to 150 patients—a responsibility much too great for his years and his experience. He has been called upon to read before he has learned to spell; he has been brought daily face to face with problems, in the solution of which he has had no experience, and to which he can bring only theoretical knowledge. As one of the consequences, he has tried every new remedy, every novel mode of treatment which has come under his notice in the periodical literature, and has developed an enthusiasm for some of them which he is surprised his elders do not share.

Compare him for a moment with one of his foreign homologues, and for convenience let us take the French. The Hotel-Dieu, at Paris, has 800 beds, and

15 internes or chefs de clinique, each of whom has under him two internes, and an indefinite number of assistant dressers, known as *stagiaires* and *benévôles*. The latter are all students, and their attendance is compulsory, for they are not admitted to the annual examinations except on presentation of a certificate of a certain number of days' attendance at a hospital. Each interne in a medical service has charge of 70 patients, each one in a surgical service has about 35. In many of the hospitals clinical lectures are given every day, and in most of the services an examination of the new patients and diagnoses of their disease is made by the attendants in turn, in the presence, and under the control of the chief. Are not these advantages far superior to those enjoyed by our young men, and are not the opportunities furnished by the hospitals extended to a much greater number than by our system?

The 800 beds of the Hotel-Dieu are in the charge of eight physicians and three surgeons, each of whom visits his wards every day in the year, except during a short vacation in the summer or autumn. The greater value of this continuous daily service to the physician needs no demonstration, and its effect in advancing medical science is equally clear.

Quite recently one of our best known surgeons found it necessary to withdraw his indorsement from certain statistics which he had published, relying upon measurements which he supposed to have been made by his house-surgeon, but for which he could afterwards find no regular authority. These statistics, if properly collected, would have had a certain value; but they are valueless now, and others like them will be. Measurements made by a surgeon have a value determined by his character for accuracy and judgment; those made by an unknown young man are comparatively worthless, because his enthusiasm, his "personal equation," has yet to be found out: and in our hospitals such statistics have to be made up by the young men because the surgeons are not on duty long enough to see the beginning and the end of their cases.

Again, I have heard that a surgeon in one of our hospitals, not long ago, amputated the limb of a patient a few days after his predecessor had resected one of its joints, and as the predecessor was proud of his operation, and waiting anxiously for the result, it is not surprising that a coolness grew up between the two gentlemen, which, however, is of less importance to us than is the loss of what might have been a valuable experience.

Now, Mr. Editor, is it not evident that our system is bad (comparatively) for the patient, the student, and the physician; that it falls short, not only of the ideal, but also of the possible?

Let us, then, have continuous service and competitive examinations. Make the places worth holding, both as a means of self-improvement and as a proof of superiority. The objection which you urge, that an impartial and competent examining board could not be found, is not, I think, well founded. Make the board a small one, and have the examinations public. The publicity and the concentration of the responsibility will prevent partiality, even if the conscientiousness of the judges should be in default, as I do not think it would be.

Let those of us who are without influence have a chance, and make it impossible for one man to hold eleven appointments. X.

DR. HEBRA has been suffering with pleuro-pneumonia, but is nearly recovered.

New Instrument.

THE ARTIFICIAL "BUBENQUELLE" OF EMS.

MR. THOMAS WARKER, of this city, has devised an ingenious apparatus for the purpose of imitating the douche of the Kräichen spring at Ems. The spring in question, as well as one of similar composition at Plombières, in the east of France, has long been noted for the value of its waters in the treatment of sterility and chronic uterine diseases. The mode of application of these waters at Ems is quite primitive, and consists simply of a bath-tub, in which is a stool with a perforated bottom, through which the douche is conducted by means of a pipe. The patient sits in a straddling position, when the douche finds its way into the vagina. The spring itself being somewhat higher than the bath in question, supplies the force to the vaginal jet by means of hydrostatic pressure.

Mr. Warker, in his apparatus, has very successfully fulfilled all the conditions necessary to insure the desired results of a local application of water of the Ems spring. This water itself is made artificially, and is contained in a glass fountain charged with carbonic-acid gas. To this receiver (as will be seen in the cut) a pipe is connected which passes through a water-

bath and thence to the bath above, across which the patient sits. The amount and force of the jet is regulated by a valve in the receiver, while the alcohol lamp underneath the water-bath raises the temperature to the desired degree. The surplus water escapes in a vessel provided for the purpose. The extremity of the jet-pipe is supplied with different kinds of nozzles to suit the different requirements of the volume and character of the stream. We doubt not that the apparatus in the hands of medical men will answer many very useful purposes, and will prove a very efficient method of treatment in all those cases of uterine diseases in which vaginal douches are indicated.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Dec. 5th, 1875, to Dec. 11th, 1875.

STERNBERG, GEO. M., Surgeon.—Promoted Surgeon, to date from Dec. 1, 1875, vice Peters, retired.

WHITE, R. H., Assistant Surgeon.—Assigned to duty as Attending Surgeon at these Headquarters, San Antonio, Texas. S. O. 225, Department of Texas, Nov. 29, 1875.

PETERS, DE WITT C., Surgeon.—Retired from active service, to date from Dec. 1, 1875. S. O. 247, A. G. O., Dec. 6, 1875.

NAVY.

November 28.

WILSON, JOSEPH, Medical Director.—Ordered to special duty at Philadelphia, connected with the Centennial.

JONES, JOHN A., Assistant Surgeon.—Ordered to the receiving ship *Wabash* at Boston.

HARVEY, H. P., Assistant Surgeon.—Ordered to the Naval Hospital at Philadelphia.

November 29.

SIEGFRIED, CHARLES A., Assistant Surgeon.—Ordered to examination previous to promotion.

FOREBEE, N. MCP., Assistant Surgeon.—Ordered to examination previous to promotion.

STREETS, THOMAS H., Assistant Surgeon.—Ordered to examination previous to promotion.

BUEL, J. W., Assistant Surgeon.—Ordered to examination previous to promotion.

SMITH, HOWARD, Assistant Surgeon.—Ordered to examination previous to promotion.

BRANSFORD, JOHN F.—Assistant Surgeon.—Ordered to examination previous to promotion.

SIMONS, M. H., Assistant Surgeon.—Ordered to examination previous to promotion.

WAGGONER JAMES R., Assistant Surgeon.—Ordered to examination previous to promotion.

December 5.

FITZSIMMONS, PAUL, Assistant Surgeon.—Ordered to examination for promotion.

HARVEY, HARRY P., Assistant Surgeon.—Ordered to examination for promotion.

PARSONS, REMUS C., Assistant Surgeon.—Ordered to examination for promotion.

NEW YORK SOCIETY FOR THE RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—The 33d Annual Meeting of this Society was held at the rooms of the N. Y. Academy of Medicine, 12 West 31st street, on Wednesday, Nov. 24, at 8 P.M.

The following named officers were elected:

President—Dr. John R. Van Kleek; *Vice-Presidents*—Dr. Jas. Lenox Banks, Dr. Samuel T. Hubbard, Dr. Isaac E. Taylor; *Treasurer*—Dr. Jas. W. G. Clements.

Managers for a term of three years—Drs. Jared Linsly, Gouverneur M. Smith, Samuel S. Purple, Thos. F. Cook, Joel Foster, Edw. L. Beadle, and Jas. O. Smith.

The permanent fund of the Society amounts to \$107,032.87. The Society extends semi-annual aid to seven widows and five children of deceased members.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

[THE MEDICAL RECORD is published every Saturday. Notices of meetings, lectures, operations, etc., intended for publication in this bulletin should be received at the office, 27 Great Jones Street, one week previous, to insure their appearance.]

Monday, Dec. 20.—N. Y. Academy of Medicine, Section of Obstetrics, etc., No. 12 West 31st st.—N. Y. Society of Neurology and Electrology, election.

Wednesday, Dec. 22.—N. Y. Pathological Society, College of Physicians and Surgeons, 23d st., corner of Fourth av.

Friday, Dec. 24.—N. Y. Medical Journal Association, No. 12 West 31st st.

Original Communications.

BACTERIA: THEIR NATURE, AND RELATION TO DISEASE.

By THOMAS E. SATTERTHWAITTE, M.D.,

SURGEON TO THE DEMILT DISPENSARY, ETC.

(A portion of this paper was read before the Medical Society of the County of New York, Nov. 22, 1875.)

PART II.

THERE is one fact to which a mere allusion has been made, and another that has not yet been mentioned, both of which must be briefly stated, otherwise we shall not be prepared to understand the relation of bacterial organisms to certain definite forms of disease.

The one is the relation of bacteria to putrefaction, and the other to septic processes. It is generally known that Pasteur formerly held that fermentation and putrefaction were initiated by organisms, but it appears, according to excellent authority,* that he has been obliged to alter these views, for it has been shown that "grapes suspended in an atmosphere of carbonic acid will undergo fermentation so as to generate alcohol and other products, even without the presence of torulae and other organisms." The experiments of Le Chartier and Bellamy have also shown that in some forms of fermentation independent organisms are often at first absent, though they afterwards make their appearance.†

In regard to putrefaction, Miller‡ also has shown that if fresh eggs be put into a basket with rotten ones, the former will soon be contaminated, showing that contamination takes place through the air. He then injected fresh eggs with a fluid containing bacteria, but not putrid; the eggs remained unchanged, showing apparently that bacteria of themselves do not necessarily produce decomposition.

But it is alleged that in the processes called septic there is always evidence of the presence of bacteria, the intensity of the affection and the limits of its spread having a close relation with the existence of such bodies. These processes may be advantageously studied by inoculating animals with various putrescent substances, such as infusions of muscular tissue, the sputa of phthisical patients, the scrapings of anybody's tongue, which soon become very offensive. These all, when introduced into the tissues of animals, such as rabbits, produce a peculiar train of symptoms, characterized by extreme constitutional disturbance, culminating frequently in death, most often at the end of forty-five to forty-eight hours, the lesions being a focus of inflammation with extensive effusions of serum about it, thrombosis of vessels, and if death do not occur at an early period, the formation of a foul deposit, consisting of pus and granular debris, with which are associated myriads of bacteria, in more or less active motion. Whether these putrescent substances or the fluids of septic diseases are inoculated, the results are about the same.

These poisonous substances generally, if not always, contain bacteria, or are a favoring medium for them, and experiments have shown conclusively that when sepsis is produced by them, its lesions are accompanied almost invariably by a coextensive spread of bacteria.

Upon this point there can be no doubt; but the ques-

tion has always remained whether the poisoning is of itself produced by the bacteria, or some other substance present, but not bacterial in nature.

The experiments of Panum,* of Copenhagen, have been directed towards the solution of this question, and they appear to be the most complete that have been recorded. He seems to prove that influences such as will kill bacteria (for the rod forms do not appear to be able to withstand the temperature of boiling), do not prevent the inoculability of septic matters. He boiled putrid matter that had produced infection in rabbits, maintained the boiling temperature eleven hours, and then subjected it to various other conditions, but the liquid still was virulent.

Onimus‡ and Miller‡ have worked in the same direction. The former claimed to have shown that the poisonous quality of putrid blood might be independent of bacteria or vibriones (by vibriones meaning probably some form of the bacteria already described, and not the long and bent filaments that have lately received this name). He also showed that blood with these organisms might still be innocuous. He concluded that the poison was an albuminous substance, though this conclusion does not appear to have been warranted by his experiments.

Miller proposed to himself the following questions:

Do bacteria possess the property of exciting inflammation when they are present in living tissue?

Or, if in the blood, do they cause fever?

Can bacteria multiply in living tissue?

Do they have the capacity of penetrating living organs?

His experiments were conducted on animals, and he used the bacteria obtained from various kinds of decomposing substances. The animals exhibited no septic symptoms, though on the second day the temperature rose, but not over 2° Fahr. On the third day, when the points inoculated were opened and examined, some shrivelled bacteria were found, but on the eighth day there were none. When bacteria were introduced into the blood currents they gradually disappeared, and finally could not be found at all, though in blood exposed to the air they multiplied rapidly. Two points have thus come vividly into notice.

1. The symptoms and lesions of putrid poisoning just described, and those of septic diseases, as frequently described, in so far as experiments on animals are concerned, resemble each other so closely that no differential marks can well be shown.

2. That bacteria are not necessarily associated either with putrid infection or sepsis.

It is convenient here to notice a plan that has been adopted by some experimenters, by which very important advances have been made in determining the nature of the poisonous matter, though chiefly in vaccine virus. It appears that Chauveau was the first to carry out the plan successfully, though Sanderson had previously employed a less perfect method.‡ It had in view the absolute isolation of the virulent principle, the method being *diffusion*. Sanderson attempted to determine if the poison of the cattle plague was crystalline or colloid. He passed the virulent fluids of these animals through parchment-paper; the diffusate was wholly innocuous, the liquid that remained behind very poisonous. He therefore argued that the *contagium* were colloid. This conclusion, however, was unwar-

§ Twelfth Report of the Med. Off. of the Privy Council, 1869, p. 22

ranted, as also that of Onimus in the plan already described, because it is now known that albuminous substances will sometimes pass through a membrane in small quantities, especially in the presence of the carbonates and phosphates (Graham* and Schumacher†), and therefore neither Onimus nor Sanderson could conclude that the fluid which remained behind the membrane, and was poisonous, owed this quality to the albuminous substance, for it is very probable that there was also albumen in some form in the clear filtrate that was harmless. This error was early observed by Sanderson.

The precise points in Chauveau's inquiry were, whether in vaccine lymph the infectious principle resides in the leucocytes, the liquid, or the minute particles contained in it. He first employed a method called *subsidence*, which had the effect of separating the leucocytes. Ten volumes of water were added to the lymph, and then the mixture was allowed to stand. The leucocytes thus separated produced no lesion. To decide between the granules and the fluid holding them, he employed filtration and then subsidence, but was unable to separate them. His *special diffusion* method, however, was successful. His plan was as follows:

Taking the vaccine lymph in the capillary tube in which it was collected from the arm, he introduced it into an upright test-tube, of the form represented in Fig. No. 2. Great care was taken that the liquid did not touch the sides of the glass in the act of filling. Water to the depth of a few lines was then added, with similar precautions, and the whole allowed to stand for twenty-four hours. Although no membrane was used, yet it is said that if proper care was exercised, the liquids did not mix, except in the immediate neighborhood of the surface of junction.

All of the soluble constituents of the vaccine passed upwards into the water. At the end of the twenty-four hours the most superficial layer (*b*) was removed by dipping into it the end of a fine capillary tube. The liquid in the tube was then examined microscopically and tested for albumen. Now albumen, though held to have the least diffusibility of chemical compounds, was found in the water, the inference being therefore that no other soluble chemical matter had been left behind. This upper stratum was used for the inoculation of heifers and children, but without success, while the lower stratum (*a*) produced the disease. It therefore appeared that the poisonous quality did not reside in the leucocytes, the albumen, or other soluble chemical bodies, the conclusion being that it was in the granules. (It may here be stated that in all these poisonous liquids, the clear fluid—such as passes through a porous clay filter—is never inoculable). Sanderson carried out this method with more attention to details,

and corroborated Chauveau's conclusions in the great majority of his experiments. The fluid that was poisonous was not turbid, as it is when it contains the ordinary bacteria, but it *did* contain granules, though they were so small as to be recognized with difficulty by the ordinary powers of the microscope.

One of the very best methods to determine the character of *contagia* is that used by Panum in his inquiries into the nature of the virulent principle in putrid infection.

The method is not difficult, and promises good results in other inquiries of a similar nature.

Panum took a putrid infusion that by inoculation on animals had been shown to produce the symptoms of sepsis, then boiled it for eleven hours, and after filtering it several times, eliminated the bacteria, as he claims, but it was poisonous. Having then taken this clear liquid and evaporated it to dryness, and extracted it with alcohol, the alcoholic fluid extract was inoculated, but no infection followed. The dry alcoholic extract or precipitate was then taken, and an aqueous extract made of it. It was inoculated, and produced septic symptoms. He therefore concludes that there exists in decomposing substances a determinate chemical substance which (*a*) is not destroyed by boiling; (*b*) is soluble in water, but (*c*) is insoluble in alcohol; though he is uncertain as to the nature of the poison, thinking perhaps it is secreted from the bacteria, and perhaps that it arises from the decomposition of albumen. He alludes to the experiments of Bergmann, who separated the bacteria from Pasteur's fluid, injected them, and got up sepsis. These same results may be observed when the bacteria from Cohn's nutrient fluid are filtered out and inoculated.

But it must be remembered that it is by no means probable that the bacteria alone are filtered out. In such a fluid, as also in Cohn's, there is organic matter; in fact the tartrate is in both, and in the fermentation which takes place soon after the fluid is made, there are a variety of new chemical combinations some one of which may be poisonous and attach itself to the bacteria, which may then be carriers of the poison, though not poisons themselves. Such arguments might be urged by those who advocate the physico-chemical theory of disease. But even this theory is unnecessary, for, as we shall see further on, we have no means of separating these minute organisms from other particles of similar size which may represent the virulent principle.

There is one point which may be noticed here, which is, that the existence of a septic condition has sometimes been founded on the temperature of the animals; but this, as shown in some preliminary experiments by Dr. Curtis and myself, may prove very unreliable. For if the tube were introduced into the rectum, as is most convenient in rabbits, the temperature was much affected by the distance it was inserted, and variations often took place for which there was no assignable cause whatever; in fact the injection of various substances beneath the skin did not exhibit thermometric results that were accorded with the character of the material used. The most reliable symptoms of infection appear to be the lesions produced by the inoculation of septic matter. This was found to be the case by Dr. Curtis and myself in a series of comparative experiments made with another object in view. The method of performing the experiments is as follows: An incision is made over the thigh of a healthy rabbit, and the muscular bundles being cut into, the material, if solid, is inserted there, the muscular fibres drawn over it, and then the edges of the skin wound are brought together. If the material be fluid, injection is made at the same point. The external wound in all cases healed kindly by ad-

* Proc. Roy. Soc., 1861, Vol. II., p. 243.

† Physik der Pflanzen, p. 128.

hesion, but when any putrid matter or unhealthy animal tissue was introduced, there would be intense inflammation at the point of inoculation, with thrombosis of vessels and extensive exudations in the neighborhood, death frequently ensuing about the end of the second day, and always, if time enough elapsed, giving rise to a thick, yellowish-white deposit, consisting of pus, granular debris, and imperfect forms of connective tissue, and generally bacteria in large numbers. At a later stage this deposit would soften, increase in amount, and give rise to a foul ulcer, which would continue to discharge for many weeks, if the animal did not sooner die during the exhausting discharge, with symptoms of diarrhoea, loss of appetite and emaciation. These phenomena are peculiarly those produced by the introduction of organic matter, especially animal, into the system, and are wholly unlike those produced by chemical irritants or foreign bodies, as experiments have shown. Injection of alcohol in considerable quantity, and inoculation of dry sand, previously superheated, produce no lesions of any note.

To determine the nature of this poison, resort was first had to filtration through common filter paper, but the results were not always uniform, though it appeared as if there was less virulence in the liquid that passed through several thicknesses of paper, yet the quality of this paper was found to vary, for sometimes no bacteria passed through a single thickness, and again numbers of them passed through four thicknesses.

Dr. Curtis then devised an apparatus by which liquids were passed through porous clay. The accompanying diagram (Fig. 3), made with Dr. Curtis's permission, is a pretty faithful copy of the original.

It consists of a porous clay cylinder, or cup (a), over the bottom of which is drawn a bit of rubber tubing (b), which is thick, and grasps it firmly; into the opposite end of this bit of tubing is fitted a rubber cork (f), through which a glass rod passes into the interior of the rubber tube. This rod is also connected with, and passes through another cork into a glass jar or receiver (c), from which the air is exhausted by the exhausting syringe acting through the fine rubber tube; when a liquid is placed in the porous cylinder or cup and the air is exhausted from the glass jar, the liquid passes through the bottom of the cup and stands in beads or drops on the bottom of the cylinder, from which it may be collected without much difficulty.

In carrying out these experiments it was found that the clear liquid that was obtained in this way from

maceration of tongue-scrappings in water, did not prove poisonous, though the tongue-scrappings were very poisonous.

The poisonous fluid always contained granules, though it did not always show the rod forms; indeed these might be removed in some instances by filtering through from four to eight thicknesses of paper, and yet the liquid was poisonous.

These experiments seem to corroborate those of Sanderson, and to indicate that the *materies morbi* lies in the granules.

Are, then, these *particulate* bodies bacteria, or other solid matters? This indeed is a difficult matter to decide, for it has been found almost, if not absolutely, impossible to separate bacteria from the other particles, with which they are so apt to be associated.

Now, if bacteria, these must be the minute forms so often described as microbacteria, microzymes, etc., but we must remember that no definite classification of these bodies has yet been made, even Cohn leaving them indefinite, so that from bare inspection by the microscope we are not able to diagnose them. Nor have we found any coloring matter that shows them satisfactorily. A method was, it is true, proposed by Letzerich* to color his "diphtheria micrococcus," but Hiller has shown conclusively that this method (with iodine) is utterly unreliable, for the very rule he adopts causes a deposit of granular iodine, which has no microscopical characters by which it may be distinguished from the minuter organisms, if present: nor have chemical means given any satisfactory results; for example, caustic soda and potassa and ammonia certainly affect bacteria but little, though they destroy most animal tissues; but they also leave certain granules unaffected, such as are found in the normal blood, which is supposed to contain no bacteria.

There being, therefore, no micro-chemical means of recognizing these bodies, attempts have been made to cultivate them, so as to see whether they are capable, as claimed, of developing higher forms. It has already been noted that Billroth speaks of the "Dauersporen," or lasting spores, as bodies that have great powers of withstanding various influences, but which when placed in sealed flasks give rise to bacteria. Can these be the same as the infectious principles that Burdon-Sanderson alludes to, and were contained in Panum's watery extract of an infusion, that had been filtered, evaporated to dryness, and extracted with boiling alcohol?

The following questions presented themselves before the final experiments were made on this matter:

1. Is the poisonous matter in putrid infusions destroyed by boiling and evaporation to dryness?
2. Is it soluble in alcohol or precipitated by it?
3. Is it soluble in water, after boiling in water and absolute alcohol?

4. If there are granules in the fluid that prove poisonous, will they breed bacteria?

These experiments, done with the co-operation of Dr. Edward Curtis, were in the main those of Panum; the liquid used was obtained by making an infusion of calf's liver that had been allowed to become putrid; the liquid and solids used were inserted in the muscular tissue of rabbits, and examined at the end of seventy-two hours.

Having established, as in previous experiments, that the putrid solution itself produced septic symptoms, and that the clear filtrate which had passed through the porous cylinder was innocuous, and also that the fluid which had passed through filter paper of different thicknesses was at times poisonous and

* Virchow's Archiv, LXII., iii., 1855.

at others not, I shall mention simply the experiments relating to the questions just enumerated.

Does continued boiling and evaporation to dryness destroy the virulence of a putrid and virulent fluid?

About nine ounces of the filthy infusion were boiled down for about five hours over a water-bath, the fluid having first been filtered so that it was quite clear to the eye. The residue was then dried and inoculated. On examination of the parts, seventy-two hours afterwards, there was found a collection of yellowish-white matter at the point of inoculation, such as had often previously been noticed in inoculation with various putrid or septic matters. In answer to the second question, *Is the poison soluble in alcohol, or is it precipitated by it?*

The residue, after continued boiling in water, was then boiled with absolute alcohol and filtered. The alcoholic fluid extract was then injected, but of the two experiments one produced a lesion and the other did not. The solid residue or alcoholic precipitate produced the customary symptoms. It was therefore uncertain whether the poison was precipitated by alcohol.

In answering the third question, which may be stated thus, *Does the aqueous extract of the dry alcoholic residue prove poisonous?* it may be said that this matter had been twice boiled in water and once in absolute alcohol. Examination of the thigh at the end of seventy-two hours showed that the same lesion was present as in the case of the unfiltered solution. There was a disseminated collection of the same yellowish-white material, with extensive exudation in the neighborhood, as observed when the matter had "taken."

In answer to the fourth question, *If there are granules in this aqueous extract, will they produce bacteria?* the final experiment was done.

It may be stated that all filtering through anything short of porous clay showed that the fluid contained granules, and in this watery extract of a substance that had been boiled in water and absolute alcohol, and washed with the latter, filtered several times, there still remained bodies of minute size, and in some instances rod-bacteria* in small numbers. To decide whether these minute bodies were capable of breeding bacteria, the "vacuum-tube" experiments were tried.

It may be stated, before going on to this experiment, that it has been definitely ascertained that fluids which are excellent media for bacteria, as Cohn's fluid, for example, will, if boiled a short time and then received into these tubes under certain conditions, not give rise to bacteria—the condition being merely that the tubes have been first superheated, their necks being drawn out and bent down, and then sealed, the air having been in great part expelled. These experiments I have had an opportunity of verifying.

The exact method of performing them was as follows: Glass tubes of about one-third of an inch in diameter were heated in the flame of a gas-lamp until one end was hermetically sealed; the flame was then passed along the tube, gradually heating it to redness, and then it was melted at about three inches from the sealed end; the melting portion was then bent round and drawn out into a fine point. Here, then, if this method was properly conducted, we had superheated the tube, expelled most of the air, and sealed it at both ends. Such is a "vacuum tube." The aqueous fluid, then, to be tested for bacteria, was heated to boiling, and at this temperature the vacuum tubes were immersed deep in the liquid; the delicate extremities were then broken off far below the sur-

face; the fluid immediately rose into the tubes, which were then slowly withdrawn from the vessel, taking care that the delicate nozzle of each was received at the level of the fluid into a pledget of cotton, until each tube was placed in a vertical position, with the nozzle downwards; this latter precaution was designed to avoid the possible contamination of the liquid with the bacteria of the air while the tube was being placed in position. Once, however, in position, it appears to make little difference whether these tubes are exposed directly to the air or have cotton over the mouths of the tubes. In this way eight tubes were filled, four of them being stopped with cotton. As a controlling experiment, that is, to show that bacteria under such conditions will grow, four other tubes were similarly filled with the same liquid—though not, of course, hotter than the temperature of the body—but to which a few drops of bacterial fluid had been added to contaminate it.

Now, this fluid, so contaminated, did not show to the naked eye the characteristic appearance of bacteria, that is, it was not turbid; but we know that if bacteria are going to multiply they will show it by the clear fluid becoming turbid in less than forty-eight hours. This controlling experiment seemed to show that bacteria would grow and multiply in this kind of "vacuum tube." Now, as to the question, *Did any such growth take place in the suspected fluid—the watery extract—that proved poisonous?*

At the end of seventy-two hours the fluid in the four contaminated liquids was turbid, and to the microscope was swarming with bacteria in the most active, independent motion.

Of the eight tubes filled with the aqueous extract, but one was at all turbid, and this merely showed a slight film upon the surface. Examined microscopically the clear fluid contained no bodies in motion, but a few motionless and shrivelled rod-bacteria.

It is proper to say here that subsequent examinations showed that of the remaining seven clear tubes several became contaminated, not turbid, but a thin pellicle formed on the surface; but others remained clear when last seen, and as the tubes with the longest necks were the clear ones—length and fineness of the neck being necessary to the experiment—it seems not improbable that some error was committed in manipulation, for it is almost impossible to carry out all the necessary precautions in each case. *It remains, however, as a positive fact*, that some of the tubes did not exhibit bacteria when bacteria would grow naturally under such circumstances. The failures, it is natural to suppose, were such as were to be expected under the conditions.

The following results appear to be authorized by the foregoing experiments:

1. That *putrid matter*, when introduced into the system, is capable of producing a well-marked train of symptoms, which are extraordinarily like those generally known as *sepsis*.
2. That the poisonous quality does not reside in the absolutely clear liquid, when entirely freed from granules.
3. That the poison is sometimes separated by coarse methods of filtration, that is, through common filter paper, though on this point the results were not sufficiently uniform to establish certain conclusions.
4. That continued boiling and evaporation to dryness will not destroy the poison.
5. That continued boiling and evaporation to dryness, and boiling with absolute alcohol, will not destroy the poison.
6. That the dry alcoholic extract, freed of alcohol

* These were doubtless dead, as they cannot survive boiling.

by evaporation with heat, was poisonous. (The liquid alcoholic extract furnished uncertain results.) So far as this experiment may be relied upon to show the albuminous nature of the poison, it is uncertain, for while the alcoholic precipitate (in which, doubtless, the albumen would be) produced poisonous results, it still remains uncertain whether the liquid alcoholic extract was poisonous or not.

7. That of putrid matter which, after several filtrations, was boiled down to dryness, then boiled with absolute alcohol, again dried and extracted with water, the filtrate was poisonous.

8. That this aqueous extract failed in a number of instances to produce bacteria, under circumstances which were favorable to the development of bacteria; and hence the granules, which are the bodies most likely to represent the poisonous principles, appear not to be bacteria or their spores.

I regret that the unavoidable haste with which this paper was completed prevented these latter experiments being carried out with desirable fulness, and that the results, especially with reference to the development of bacteria in these poisonous infusions, can only be regarded as preliminary. If the results in such cases corroborate those just stated, then it would appear that the evidence against bacteria, as the causes of putrid infection, is almost, if not completely, conclusive.

But even if the friends of the germ theory were to find a different state of things—that the vacuum tubes were filled with bacteria—this can give them little satisfaction. For in all such infectious fluids we find granules, or minute microscopic bodies; but since as yet we have reached no method of distinguishing them, we can never be sure that it is not these other bodies that cause the trouble, while their "micrococcal companions" are occupying themselves with rapid multiplication.

And now for the most important general arguments brought forward in favor of the germ theory in its application to various affections.

1. It is said of pyæmia, erysipelas, puerperal fever, and hospital gangrene, and such other diseases as are regarded as septic, that there is a very constant relation between the number of the bacteria present and the intensity of the disease, and that where the changes are most active, bacteria are most numerous.

2. The development and rapid spread of such diseases is most easily explained on the supposition that they are produced by living units rather than by anything else we can conceive of; for it is estimated that the multiplication of bacteria is so rapid that an ordinary bacterium dividing in about one hour, would at the twenty-four hours have originated over 16,000,000 of its kind.

3. No products of the laboratory produce fever, but only such liquids as contain bacteria, or have a fondness for them (Sanderson).

4. The power of retaining active qualities that the poisonous matters show is explainable on the ground of their being bacteria, which have this peculiar property to a wonderful degree, while minute portions of the body, when separated from it, die in a short time.

6. Minute organisms are now generally admitted to be the sole and sufficient causes of diseases, such as scabies, favus, and the like, and our knowledge of various epidemic diseases among plants and animals has led to the general belief that they also are produced by minute organisms.

In reply to these arguments or points in evidence it may be said: 1. That such organisms do unquestionably exist in the diseases referred to, but it is also now

known that they occur in health, the entire mucous membrane from the mouth to the anus being often peopled with countless myriads of them in some form or other, and generally in active independent motion. These facts are now generally admitted, as every one who has a good microscope can readily prove for himself.

But it is claimed that bacteria also penetrate the tissues some little distance, at least that they get into the lymphatics from the intestine, which is by no means inconceivable, for it is well known that if persons live continuously in a smoky atmosphere, as in cities where coal is extensively burned, the bronchial glands become the seat of extensive collections of carbon, showing that particles of considerable size can find their way through the lymphatics into the glands.

That bacteria do also get into the general circulation in some of the lower animals is a fact that is now scarcely disputed, and it is further stated by Wagstaffe and others,* that they have seen them in the human blood in health. But that they also are found in other conditions than those of special disease, appears from the fact that they have been found in the pus of acute and chronic abscesses.†

The mere fact that bacteria have a numerical ratio to the intensity of a disease, or its most active changes, may not be anything but a concomitant phenomenon, especially in view of the foregoing facts.

2. In reply to the objection that the multiplication of a contagious matter cannot be compared to anything that is not living, it is said that chemical processes may imitate it, for, according to Bastian,‡ "the crystals of sulphate of soda may multiply when a fragment of such a body is thrown into a complex liquid which contains its component parts, or the liquids of the body acted upon by the original source of contagion may be brought into contact with the various tissues of the body." It does not appear, however, that we are forced to any such assumption as the former.

3. As for the fact that no product of the laboratory produces fever, it is by no means certain that we shall not find such; we must admit, however, that contagious fluids have a proneness for bacteria.

4. These extraordinary qualities that have been noted are, in a measure at least, possessed by certain vegetable poisons, such as woorara, and certain animal poisons, such as that of the cobra, analyzed by Fahrer, of India, and of the rattlesnake, studied by Weir Mitchell. Fahrer has made most extensive experiments, and found of the poison of the cobra that it may be diluted with water, or even ammonia, or alcohol, without destroying its deadly qualities. After keeping it dried for months it was found also to have retained its virulence; qualities which are extraordinary like those observed in the contagious principles of putrid matter, as already noticed.

5. Bacteria which cannot be distinguished in the experiments cited from those of disease, have been introduced into the system in numbers without producing any lesion whatever.

It seems to be definitely proven, in many instances, that the infecting quality of a substance is not destroyed by continued boiling and absolute alcohol, which are known to destroy the reproductive character of bacteria of definite forms, though it will be admitted that it may require more extended observations to determine whether such influences will prevent the

† Med. Press and Circ., Mar. 10, 1875.

‡ Lancet, April 10, 1875.

development of bacteria from the very minute bodies that are claimed to originate the definite forms.

One of the most remarkable facts in this connection was observed by Dr. Edward Curtis, while experimenting on the best method of neutralizing or destroying the poisonous action of putrid substances. Both he and I had established, independently, and, as it appeared to us, satisfactorily, that salicylic acid, in the proportion of 1 to 100, with a little phosphate of soda as a solvent, and carbolic acid of the same strength, have, each of them, the power of preventing the formation of bacteria for a period of two months* at least. This known anti-microphytic power of salicylic acid was then utilized to determine if it would also prevent infection if mixed in a concentrated form with such poisonous matters as tongue-scrapings. It was found, extraordinary as it may appear, not to have any effect upon the poisonous quality of the matter, and the lesions, though without bacteria, appeared as usual.

These experiments I believe to have been the first that reached this result in regard to salicylic acid. They were carried out in a somewhat different way by Dougall,† of Scotland, as reported in July last, subsequent to Dr. Curtis's experiment. Dougall found that while carbolic acid in concentrated solutions prevented the development of ordinary bacteria, it under certain conditions suspended, but failed to destroy, the virulent properties of vaccine virus.‡

In the matter of salicylic acid, confirmation of these results has been obtained from Von Gulik,§ of Germany; for after many experiments with lymph virus, which, kept in capillary tubes, only lasted with him from fourteen days to a month, it was successfully preserved by him in glycerine about two months, but not more, though salicylic acid kept it over a year.

These experiments, though done with a different view, singularly suggest that these remarkable substances—salicylic acid and carbolic acid—while excellent preservatives and anti-microphytics, are perhaps not disinfectants at all in the strict sense of the term.

Let us now briefly review this question in its relation to a few special diseases, which have been recently investigated with the aid of the most recent modern appliances by scientific experts whose opinions are in every way worthy of respect. I refer to anthrax, or the carbuncular diseases of the French, sheep-pox, small-pox, relapsing fever and typhoid.

The name carbuncular diseases, as applied by the French veterinary surgeons, includes a remarkable class of contagious affections, not very clearly limited, but including such forms as anthrax or malignant pustule, splenic fever, and mycosis intestinalis. All these affections show post-mortem appearances that are extraordinarily similar. Balls of round spheroids are said to be found in the diseased tissues, and rod-shaped bodies in the circulating blood, particularly in the portal vein; the spleen is enlarged, there are hemorrhagic infarctions of the intestines causing the mucous membrane to slough off, extensive serous exudations and infiltrations, and hyperemic enlargement of the glands in the neighborhood of the affected parts. The appearance of a pustule (malignant pustule) appears to be common in these cases, but is not a constant appearance; all these symptoms often leading to a fatal termination, though the pustule be absent.

It is in these diseases that Davain* called attention

to the presence of minute rods,* which he called bacteridia. He said that they preceded the morbid symptoms, and when the bacteridia of decomposition appeared the contagiousness of the blood ceased. They were so numerous, according to this author, that it was estimated from eight to ten millions existed in a single drop of blood, and he claimed that he had produced the disease by the inoculation of the millionth dilution of such a drop.

But he was met by a number of opponents, among them Bouley,† Gaillard, and others, who contended that the rods were very often absent, and yet the blood without them had infecting qualities. This, with our present knowledge, is not difficult to explain, especially as he gives no special distinguishing marks to separate them from ordinary rod-bacteria, and we know that they may exist in health, especially in the blood of the lower animals. Bollinger himself, an excellent authority, while favoring the view that the disease is due to minute organisms, admits that he has inoculated animals successfully with fluids that did not contain the rods, and he cites Branel to the same effect; Bouley, Leplat, and others also agree on this point. But Bollinger tells us that the infecting fluid always contains spherical bacteria, that is, such minute bodies as by cultivation might produce rods.

This brings us to a point that we have reached in regard to putrid infection. It is clear that the infecting matter is not necessarily in the rods, but *is it in granules which subsequently produce rods?* Let us, however, first glance at small-pox, sheep-pox, and vaccine.

There is probably no subject that has been more closely inquired into by a large number of observers than the contagious principle of these diseases, and it appears to be likely that the alleged forms are the same in all. Some ten years ago it was noticed that vaccine lymph contained minute spheroids, accounts of which were published in 1867-1868,‡ and to which Cohn gave the name *microsphaera vaccina*.

Their multiplication in the field of the microscope and their chemical properties led them to be regarded as the *micrococcus*. They were found in the early stage of the disease, before the eruption, and hence were thought to have some causal relation with it. Chauveau attempted to separate them from the lymph, and he appears to have shown by his experiments that the virulent principle is both *insoluble* and *non-diffusible*. Sanderson, who followed out Chauveau's researches, while he comes to the conclusion that the matters are insoluble, says that he has found them "filamentous, not jointed, but branching and giving off from their extremities microspheres or conidia, much after the fashion of the penicillium."§ Cohn found them as small, colorless cells, sometimes in rosary-like chains of eight or more links, and sometimes in heaps.

The weak point in all this evidence, however, is that no sufficient line of distinction is drawn between these bodies and others that would exactly correspond to this description, and that are found in other matters,—an argument which is applicable to the whole doctrine of bacteria in relation to disease.

Relapsing fever is one of the strongholds of those who maintain the microphytic theory of disease. In 1872 Obermeier, of Berlin, published a list of thirty-two cases in which he had observed that the blood was constantly the abode of long filamentous bodies called *spirilla*. They appeared during the rise of the fever,

* At the end of eleven weeks the fluid was still free from bacteria.

§ Loc. cit.

and disappeared with its fall, and again occurred during relapse. These observations have been confirmed by numbers of persons, though denied by Lapt-schinski.*

This whole subject is so comparatively new that it is almost too early to look for records of further investigations on this point. The spirilla may indeed be pathognomonic of the blood of relapsing fever, but it is certainly a remarkable fact that Ponfick, of Berlin (whose authority I feel, from personal acquaintance, to be of the best), should *not* have found them in the most marked lesions of the disease, for he tells us that the embolized and enlarged spleen is one of the chief causes of death,† and yet the emboli did not contain them, as we should have a right to expect. We must finally note that Klein, of London, has announced that in typhoid fever he has discovered peculiar bodies at or near Peyer's patches. These bodies were carried along the lymphatics or blood-vessels of the mucous membrane. Their bodies were often of a yellowish-brown color, and in size from one-fourth to three times the size of a human red blood-corpuscle. These bodies have not, so far as I have known, been seen by any one else.

There is one general fact that may be derived from the review of this question of contagious principles in small-pox, carbuncular diseases, relapsing fever, and typhoid—and this is, that we have no reliable evidence that the definite forms described are capable themselves of producing the diseases in question.

But assuming, as some would have us believe, that the diseases, if not produced by the filaments, chains, or heaps, are produced by minute forms that will produce such filaments, chains, or heaps, then our conclusions have to be derived from the effect of these granules by testing their physiological action, as has been shown by the use of vacuum tubes, and unless the granules in question respond to such tests as these, we have a right to doubt their being the germs of bacteria.

I have tabulated the following general conclusions, that appeared to be warranted by the investigations made in this direction:

1. Bacteria are certain vegetable organisms which belong probably to the algae; they are found abundantly in nature, but chiefly where there is moisture.

2. They exist in the body in health, covering the mucous membranes from the mouth to the anus, and sometimes appear to penetrate a certain distance into the system, without causing symptoms of disease.

3. They also exist in putrefying fluids, and in various disease processes, occurring in hot and cold abscesses, in the blebs of erysipelas, and in simple blisters.

4. It is doubtful whether the virulent principle of infective diseases is albuminous.

5. This principle does not reside in the perfectly clear fluid that passes through porous clay. In putrid infectious fluids this appears to be certain. The poison is rendered less virulent by repeated filtrations through common filter-paper.

6. The virulent principle may be boiled for hours, filtered numbers of times in the ordinary way, boiled with alcohol, and again filtered and dried, and yet the watery extract of such a dry residue will produce septic symptoms. It is therefore soluble, or at least suspended in water.

7. The liquid which is thus poisonous may be clear to the eye, but contains granules under the microscope.

8. These granules have not produced bacteria in a number of instances when they were placed in a suitable condition to do so.

9. We cannot, therefore, feel that satisfactory evidence has been brought to show that in any of the diseases or processes enumerated, minute organisms are the sole and sufficient causes of disease.

Progress of Medical Science.

GENERAL ATROPHY OF ONE EXTREMITY, THE RESULT OF INJURY.—MM. Desnos and Barić report the following interesting case, from the Hôpital de la Pitié, in Paris: The patient was a man 56 years of age, who, some five years before his admission to the hospital, had his right foot bruised by the wheel of a cart. The wheel passed obliquely across the instep, causing a pretty severe contusion, from which, however, the patient sufficiently recovered in a few days to resume his occupation, though still somewhat lame. Fifteen months after the injury the lameness had not disappeared, and the patient noticed that the limb on the affected side had become considerably wasted; the thigh especially had grown smaller, and the whole limb appeared shortened. On admission to the hospital it was ascertained that the right limb measured, from the anterior superior spinous process of the ilium to the external malleolus, about one inch and a half less than the left. From the anterior-superior spinous process of the ilium to the head of the fibula, the right limb measured one and one-eighth inches less than the left, and from the head of the fibula to the external malleolus the difference between the two sides was three-eighths of an inch. The circumference of the affected limb was markedly diminished both at the calf and at the thigh. Moreover, there was a distinct flattening of the muscles of the buttocks on the atrophied side. At the middle of the calf the difference between the two sides was three-eighths of an inch; just below the patella and condyles of the knee it was three-fourths of an inch. At the middle of the thigh the difference was over four inches, and higher up about one inch. In walking, aside from the lameness, there was nothing particularly noticeable in the gait. The affected limb was much feebler than the other, was easily fatigued, and was incapable of supporting the weight of the body. In standing the patient rested entirely upon the left leg. Certain movements of the hip, knee, and toes, on the affected side, caused some slight pain, and occasionally the patient complained of a crackling in the knee when moved suddenly. When lying upon the abdomen he experienced momentary pain in certain portions of the limb—sometimes in the calf and sometimes in the thigh. In addition to the above symptoms the patient also complained of frequent sensations of cold and pricking, especially in the foot and in the lower part of the leg. Neither anesthesia nor analgesia could be detected, unless perhaps a very slight diminution of sensibility in the right limb. The skin and nails appeared perfectly normal. The electric contractility of the muscles in the atrophied limb was slightly diminished, most markedly in the muscles on the posterior aspect of the thigh. Of the original injury on the back of the foot no trace whatever remained.

With regard to the pathology of the above case the

* Centraltblatt, 3, 1875. Irish Hosp. Gaz., April 1, 1875.

† Anatom. studien ueber den Typhus recurrens. Verchow's Archiv, May, 1874.

writers adopt the view that the muscular atrophy which follows traumatic lesions of the nerves is due to the diminution or suppression of a trophic influence derived from the nervous centres and conveyed to the muscles, not by the special trophic nerves of Samuel, but by the musculo-motor nerves themselves. Hence in the above case it is supposed that in consequence of a contusion or laceration of filaments of the musculo-cutaneous and anterior tibial branches of the sciatic, a morbid change was induced at the spinal root of the nerve (Vulpian), which was communicated to the adjoining gray matter, and thence was transmitted to the nervous trunk, causing atrophy of the muscles to which the fibres of the nerve are supplied. It is especially remarkable in this case that not only the muscles, but also the bones, were atrophied.—*Le Progrès Médical*, Oct. 2, 1875.

ALBUMINURIA.—In a communication on the above subject to the Congrès périodique international des Sciences médicales by Professor Mariano Semmola, of the University of Naples, the presence of albumen in the urine is regarded as merely a symptom, and one which does not necessarily imply organic disease of the kidney, since it is occasionally met with under purely physiological conditions. Thus the urine may become albuminous after the injection of a considerable amount of albuminoid substances, or the condition may be produced in an animal experimentally by covering the body with an impermeable coat of varnish, thus suppressing the functions of the skin.

S. distinguishes three forms of albuminuria: The first is mechanical, and depends upon increased intravascular pressure from derangement of the renal circulation, and is frequently the result of cardiac disease. The second form is described as dyscrasic. It depends upon a dyscrasia which causes such an alteration in the albumen of the blood that it is rendered incapable of assimilation, and is, therefore, expelled from the economy. Of this nature is the albuminuria observed in the course of tuberculosis and syphilis. In its third form the albuminuria is of a mixed character, partaking of the characters both of the first and of the second forms, the disturbed renal circulation combining with a dyscrasia, and the condition is then known as *Bright's disease*. Its usual cause, it is claimed, is exposure to damp and cold. This operates in two ways: The chilling of the surface causes a determination of blood to the organs in the interior of the body, and congestion of the kidneys results. Secondly, the suppression of the functions of the skin from the same cause gives rise to a dyscrasia in which a portion of the albumen of the blood is prevented from being assimilated, and is discharged with the urine. It is claimed, moreover, that according as the influence of cold and wet is brought to bear upon the economy, rapidly or slowly, will the disease be acute or chronic; in the former case the dyscrasia is more pronounced, while in the latter the chief element is the increased intravascular pressure in the kidneys.

The most important characteristic of Bright's disease, according to the writer, is the diminution of the amount of urea in the urine. No such diminution occurs in the purely mechanical or dyscrasic forms of albuminuria, or at least in a much less degree. Hence it is regarded as a pathognomonic symptom of Bright's disease. The pathology and symptoms of the albuminuria produced by alcohol, gout, and scarlatina are declared identical with those of Bright's disease.

In accordance with the above views of the pathology of the disease, the following is the treatment proposed:

1. The patient is enjoined to abstain, as far as possible, from all albuminoid foods, and a milk diet is prescribed.

2. To promote the cutaneous functions hot-air baths are advised, followed by a cold douche, and afterwards moderate exercise.

3. As adjuncts to the above measures large doses of iodide of potassium and inhalations of oxygen are recommended. The ferruginous preparations are esteemed useless, for the reason that they are not assimilated.—*Le Progrès Médical*, Oct. 2, 1875.

SUCCESSFUL TREATMENT OF ACUTE TRAUMATIC SUPPURATIVE INFLAMMATION OF THE KNEE-JOINT.—From the *Schweiz. Corr. Bl.* of 1874, Dr. Asché quotes brief histories of three cases illustrative of the treatment of acute suppurative inflammation of the knee-joint of traumatic origin. The first case, reported by Prof. Socin, of Basle, concerned a butcher of twenty-four, who four days before had wounded his left knee with a sharp knife, laying open the joint. After binding the knee with a wet cloth he went on with his work, and at night walked home. When seen by S. the temperature was just short of 104° F., the knee was partly flexed, and at about an inch from the inner border of the patella was a sharply cut wound about one-fifth inch long, from which thin fluid escaped on pressure. There was fluctuation in the joint. The limb was put up in plaster-of-Paris in an extended position. The fever increasing after three days, the wound was dilated and an incision made along the outer border of the patella, and a drainage tube earned through it; at the same time extension up to thirty-five lbs., and counter-extension up to fifteen lbs., were applied. At the end of twelve hours the temperature had fallen to 100° F. Other incisions were subsequently made into the joint, but the tube and extension apparatus were removed after eighteen days. At the end of two months and a half after the receipt of the injury the patient could extend his leg vigorously, and flex it up to 80°. In the second case a carpenter of twenty-five had inflicted a wound with an axe on his left knee, and had continued working for some days. When seen by Dr. Sterchi, at the end of seven days, there was a wound of an inch long at the inner border of the patella, from which pus and synovia escaped; the joint was painful; no bare bone could be detected; the fever was moderate. An extension bandage and carbolic-acid dressing were applied, and recovery ensued. It should be observed that this patient was not treated in an hospital. A third case was that of a butcher, wounded in the knee with an axe. Suppuration set in, and an incision was made under carbolic acid into the distended capsule of the joint. Recovery followed under the use of carbolic-acid dressing. Thus it appears, says the commentator, that in individual cases the antiseptic treatment of suppuration of the knee-joint may be of service, although as a rule it is not possible in this way to prevent destructive suppuration of large joints when suppuration is already present. Permanent extension can produce a diminution of the intra-articular pressure only in cases where the ligaments of the joint and the muscles of the limb are much relaxed, taking off the pressure from the granulations and fluids in cases where the joint is closed, and when it is opened favoring suppuration and the escape of secretions. Still further advantages are found in preventing motion, improving the position of the limb, and changing the points of contact of the cartilages, and in preventing infiltration of the soft parts. Puncture of the joint should precede extension.—*Schmidt's Jahrb.*, Sept. 8, 1875.

THE MEDICAL RECORD:

A Weekly Journal of Medicine & Surgery

GEORGE F. SHRADY, A.M., M.D., Editor

PUBLISHED BY

W. L. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, December 25, 1875.

THE PROPHYLAXIS OF DIPHTHERIA.

In our leader of last week we called attention to the remarkable association which outbreaks of diphtheria are apt to have with filth-nuisances of some sort or other, and we urged the importance of planning means to abate them. It may be that we have not sufficient facts to justify us in accepting definitively the doctrine of a filth origin for the disease, even in those cases where the question of contagion is hardly to be thought of, and yet it seems that the evidence in support of the filth theory is getting stronger day by day, and it is certainly strong enough to warrant us in attacking the presumed source of the trouble. Success in this direction will also have another merit—that of mitigating or diminishing other diseases whose relation to filth is more clearly defined.

We must realize, however, at the outset, that sanitary measures can only be prosecuted to advantage by a sort of compact on the part of each individual with the proper authorities. Neither can accomplish much alone. Each householder must look to his sewer-pipes, closets, cellars, and the general good condition of his premises, while the authorities should see that the soil is properly drained, the waste carried off and properly disposed of; that gases do not force themselves into the house; that the water supply is not contaminated; and that public nuisances or evils are restrained or stopped.

We have no hesitancy in saying that a vast deal has yet to be accomplished by our public boards. In the matters of drains and sewers alone great reforms are needed.

Our ignorance of the natural water-course system of the city is a matter of common acceptance, while it seems to be conceded that in putting up buildings little or no attention has been paid to the matter. As for our sewers, we know that they have often been badly built, and are even now very prone to pour out their gases into

our houses. As for the manner of making sewer connections for our houses, it has been left pretty much to the fancy of the builders.

Still, desirable as it may be to have good sanitary systems inaugurated and efficiently carried out, we can hardly expect them in the near future. The expenses and the doubtful efficiency of such measures will always be urged against them by those who have control of the public moneys, and yet it is no less important that we should look these matters in the face. The statement of Mr. Simon, Chief Sanitary Officer of Great Britain, is a rather startling one to consider. He says that of 1,000,000 deaths occurring in England, fully 125,000 are from preventable diseases; or, in other words, that one out of every eight deaths might have been prevented by the application of facts known to scientific men. Loss of life means loss of money to a community, and the actual amount can be computed with tolerable accuracy in dollars and cents. Fortunately we have an excellent example of the actual gain to a locality from carrying out an efficient sanitary system. The English town of Croydon was very unhealthful at one time, so much so, in fact, as to lead to the establishment of a pretty complete set of public works and the enforcement of special sanitary regulations, all of which have been in operation some fifteen years. The mortality before the completion of the works was 23 per 1,000. Afterward it was 18 per 1,000 for an average of thirteen years. This gain of five per cent. represented about 2,500 lives, and it has been estimated that the gain to the town from these lives saved during thirteen years was fully twenty-five per cent. more than the sum spent on the public works.

It is often hard to enforce truths like these on everyday thinkers, unless the advantages take the hard form of an actual gain or loss in money; but it is certain that the results of good sanitary work represent so much money actually saved to any district where it is applied.

But, after all, such measures are useless, if each individual does not do his part toward securing the common object; and, in fact, the best protection that any householder can have will be the result of careful attention to the sanitary condition of his own premises. In the great majority of cases he may be sure that his chances of disease will be very materially lessened.

The importance of these matters to us at this time is not to be underestimated.

Diphtheria has been prevailing extensively among us for several years, and the weekly mortality has been, as usual at this time of the year, gradually increasing from the low stand it took in summer. During last October the mortality for a single week was 54, which is higher than during any week in October of last year, and very far higher than the average of any week in October for the past five years. Fortunately this alarming rate of increase has not been sustained; in fact, the mortality for the week ending Nov. 27 was

still at 54, though this is higher by five than for the corresponding week of last year.

Such facts show us that diphtheria is still present with us in a very deadly form, and our vigilance in watching for the treacherous enemy should not be relaxed, each one seeing that no door is left open to admit him. To know the subtle ways of the disease, and so to guard against them, is our best means of protection; early and appropriate treatment may doubtless modify, or perhaps arrest the disease in some instances, but when once the poison has entrenched itself in the system medical skill will be of little use.

The general measures that have been suggested are easy enough to understand when once the evils are known.

Attention to sewer pipes seems to be a matter of the greatest consequence, and as they have been frequently left open in erecting buildings, they should be most carefully examined. A case of diphtheria broke out recently in one of our most elegant houses, and the attack was fatal. In this house, where every attention had apparently been paid to sanitary conditions, there was a deficient sewer-pipe connection, so that the sewer gas, escaping in large quantity, was taken into the air-flues and so diffused throughout the house. In another case a brick drain covered with loose flagging passed under the furnace, and the gas was sucked in just as in the former case, and so carried with the hot air up into the house. These house drains of brick are specially dangerous, and it has been recommended that glazed or iron pipe be in all cases substituted for them. The smaller escape-pipes are also often apt to be overlooked, such as those that carry off the drip from under wash-sinks and basins: they are so rarely used that, if trapped, the water in the traps will soon evaporate, and then no barrier would be offered to the sewer gas. They should be kept tightly stopped or permanently closed. One of the best plans appears to be that of having one large trap to the house soil-pipe between the house and the sewer. This will prove an almost impassible barrier for all gas from the sewer; but, lest it should still enter, the soil-pipe may be ventilated by carrying from it a small tube through the roof, or into one of the chimney flues, preferably the kitchen one. We are also told that water-closets should be in parts of the house where they may freely communicate with the open air, so that they may be constantly kept sweet and odorless. One of the most important additions to any house is a tank upon an upper floor, so that there may at all times be a sufficient head of water to flush the basins and traps. The overflow pipe from the water-tanks should not communicate with the sewer or its connections, lest the gas find its way through it into the water. Various remedies are suggested for this, such as trapping the pipe, or leading it indirectly to the sewer. Perhaps it should escape independently or with the rain water from the roof. Cellars are now receiving special at-

tion, and they should not only be thoroughly ventilated, but made perfectly water-tight, so that should a drain or sewer pipe in the neighborhood burst, the fluids cannot force themselves into the house.

An excellent plan, in case of suspected sanitary neglect, is to have the premises examined by some one who has had special experience in this branch of business. The services of an ordinary plumber are worse than useless.

But it is not only private houses, but private out-buildings that are sources of danger. Proprietors are apt to think that on their own premises they have a certain immunity from sanitary control. In this way they have been known to leave great piles of decomposing matter to rot for months together, even in the immediate vicinity of sleeping rooms; in one of such instances a terrible visitation of the disease appeared.

Of course next in importance to the prevention of an outbreak of the disease, is the hindrance of its spread, and here a fair amount of success is assured us by proper quarantining. Adults take the disease comparatively rarely, and so they suffer less danger from attending on the sick. Children under two are specially prone to the disease, chiefly those between three and six. All children, therefore, should either be sent away or kept at a distance from the patient. The danger of carrying the disease upon the person is probably slight; those that have been in the immediate neighborhood of the patient have taken the disease most often, perhaps, from the sputa or breath. Such solid matters coming from the patient may, perhaps, best be destroyed by fire. It seems hardly probable that efficient disinfection can be carried on in the sick-room by the use of the ordinary disinfectants. If used in sufficient quantities to disinfect, their influence upon the patient would probably be injurious. Much, however, may be done by the introduction of fresh air in abundance, by which much of the poisonous matter can be removed. Water, also, is excellent, so far as it is used to keep the patient clean, and so diminish the danger of his being a centre of infection. Flowing water in the room seems to act extraordinary well, perhaps by withdrawing with it the poisonous exhalations in the air. When matters are to be taken from the room, disinfectants may be freely and advantageously used, and chlorine is now regarded as one of the most efficient means at our command. The common bleaching powder, to which a little acid is added, is the ordinary way of securing the evolution of the chlorine. Whenever the attack is over, the rooms may be fumigated or cleansed by a variety of different methods, but perhaps chlorine, for household purposes, will be found most effectual. The treatment of catarrhal affections of the air-passages; especially of children during the prevalence of diphtheria, has been recommended, and it appears to be a most excellent precautionary measure, as diphtheritic infection is very apt to be preceded by catarrhal symptoms.

With careful attention to such general matters it is likely that the frequency of diphtheria will be very much diminished.

THE PATENT MEDICINE TRADE.

MR. MCELHENIE favors us with a communication upon the above subject, which will speak for itself. Notwithstanding his earnest defence of the pharmacists in regard to the question, we are still unconvinced that the course which he advises is the proper one. On all the subjects to which he refers we have expressed our opinion, and his arguments rather strengthen it than otherwise. Our remarks in regard to the Health Almanac are subject to modification, since the appearance of Mr. Hoffman's admirable annual. There can be no possible objections to such an almanac, but it is not of a kind which we were led to anticipate at the time the editorial referred to was written.

HANGING AS A SCIENCE.

VERY rarely is a murderer scientifically hung. Notwithstanding the great anxiety of the sheriff to do his work properly, there is generally a slip somewhere which casts serious reflections upon his artistic skill. Sometimes the rope breaks, sometimes it is too long, occasionally there is a torturing delay from the defective working of the drop, and once in a while the knot is displaced, as in the case of one of the negroes hung last week. It is strange, too, that notwithstanding the great care taken to dislocate or fracture the odontoid process by means of the knot behind the left ear, the result is very exceptionally obtained. On the principle that whatever is worth doing at all is worth doing well, it seems quite necessary that our hangmen should study their science anew.

CLOSE OF VOLUME X.

IN closing the tenth volume of the RECORD, we take occasion to express our obligations to our contributors and to the members of the editorial staff, for the very substantial and valuable aid they have given us during the past year. Dr. Thomas E. Satterthwaite, in his superintendence of the department of progress of medical science, has supplied our readers with the best of material from our exchanges. In this labor he has received the valuable assistance of Dr. J. H. Emerson, for the German selections; Dr. Geo. R. Cutter, for the Scandinavian; Dr. E. B. Bronson, for the French; and Dr. Charles Laight, for the English. Dr. Wesley M. Carpenter has continued his reports of the medical societies, lectures, and hospital notes; and Dr. F. A. Castle, in the news department, has kept us well supplied with the latest medical intelligence from different parts of the world.

The change of form in the RECORD from a semi-monthly to a weekly has, we trust, added to its value, in not only giving us an opportunity for more

frequent issues, but in increasing the size of the journal, and in enabling us to give a proportionate amount of space to satisfy the demands of our contributors. It is unnecessary for us at this time to refer to the character of the contributions which have appeared in our columns. Coming from many of the best writers in the country, they speak for themselves. In our selection of the subjects it has been our aim not only to meet the pressing wants of the general practitioner, but many of the articles were written at our special solicitation.

In the editorial discussion of the medical topics of the day it has been our endeavor to be independent, impartial, and truthful. If at times we have erred in judgment, it is a failing which is human, and which entitles us to the ordinary charity of a just appreciation of motive. During the coming year it shall be our aim to increase the usefulness of the journal by every means in our power, and to make it even more acceptable to our subscribers.

Reports of Societies.

NEW YORK MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

Stated Meeting, Dec. 3, 1875.

DR. E. R. PEASLEE, PRESIDENT, IN THE CHAIR.

INSECTS IN THE EAR.

DR. BURRALL mentioned a case where an insect walked out when the canal was artificially lighted up by holding a lamp in front of the ear.

DR. MESSENGER calls to his aid the force of gravity in removing foreign bodies from the ear, and places the patient upon the side and throws the stream up into the ear while this position is maintained.

DR. W. T. WHITE related a case in which he removed a roach, about three-fourths of an inch long, from the ear, and it became necessary to use both the forceps and syringe. The serrated edges of the wings of the animal prevented him from backing out of the ear, and he died in the canal. The removal was piece-meal.

DR. MESSENGER related a case where a woman, *æt.* forty, weighing 200 pounds, was walking the floor in agony; constant desire to micturate; constant desire to have an evacuation from the bowels; pulse frequent; nausea extreme; headache, and considerable abdominal distention. The uterus was found in a condition of extreme retroflexion. No attempt was made to restore the uterus to its normal position, but the woman was placed upon large doses of *fld. ext.* of helonium and verbena, and within twenty-four hours she was perfectly easy. The tense, hard feel had also disappeared from the body and neck of the uterus, etc. The case was related to elicit a probable explanation of the symptoms.

DR. PEASLEE remarked that probably it was a case of retroflexion of some standing, and that for some reason the uterus had suddenly become congested, and this gave rise to the great distress.

Under such circumstances he would have no hesita-

tion in replacing the displaced organ at once. The condition is one of simple congestion, and that cannot be entirely relieved in any way so quickly as by restoring the organ to its normal position. He has never experienced any difficulty from this method of treatment in that class of cases, nor has he hesitated to use the sound, if necessary, to assist in restoring the organ; but it must be used carefully.

The Association then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, November 24th, 1875.

DR. F. DELAFIELD, PRESIDENT, IN THE CHAIR.

UTERUS AFTER ABORTION.

DR. PUTNAM-JACOBI exhibited the uterus which had been presented at the previous meeting by Dr. Finnell, and which had been removed from a patient who had been the victim of criminal abortion. At the time of the first presentation of the specimen no connection could be made out between the peritonitis and supposed injury to the cervix uteri. Dr. Finnell was kind enough to allow Dr. Jacobi to examine the specimen after the meeting, and as the result she was enabled to discover inflammation of the veins behind the peritoneum, posterior to the cervix. One of the larger veins leading into a uterine sinus was intensely injected, while another contained a fibrinous clot, showing, as it seemed, quite conclusively that the starting-point of the peritonitis was in or about the cervix.

BROKEN ELASTIC CATHETER IN THE BLADDER.

DR. D. M. STIMSON presented a portion of an elastic catheter, which had been removed by operation from the bladder of a patient a few days before. The patient was a German, about middle age, who was injured in the back about fourteen years ago. As a result of this injury he had partial paralysis of the lower extremities and of the rectum. Ever since that time he had been obliged to draw off his water with an instrument. Two months ago he was run over by a wagon, the wheel of which passed over his loins. This greatly aggravated his urinary troubles, and forced him to enter the Pennsylvania Hospital. He remained there but a short time, and coming out he purchased some cheap catheters for his own use. Shortly after this, while passing one of these, it broke in the urethra, about eight inches from the tip. The patient could feel the fragment very plainly, extending nearly to the peno-scrotal angle. He then determined to present himself to Dr. Gross's clinic, and was again admitted to the hospital, when one of the house-staff, on examining the bladder, accidentally pushed the broken catheter in. The patient being much dissatisfied with this proceeding, determined to see Dr. Parker, of this city, and for that purpose took a journey on foot as far as New Brunswick, begging a ride the rest of the way on a freight train. During all this time the foreign body was in the bladder.

When he presented himself to Dr. Parker he had a string around his prepuce, which was swollen to the size of the fist. But such was the insensibility of the parts that the patient did not seem to suffer much inconvenience. When this string was removed the urine dribbled from the urethra. Dr. Stimson, in attempting to remove the catheter by the lithotrite, broke it (the fragment of catheter) in two. A few evenings after, Dr. Parker removed the portions thus broken, and in a week afterwards Dr. Stimson extracted the remainder of the foreign body. The patient suffered

very little after the operations, and there was an insensibility about the parts which was rather remarkable.

SACRO-ILIAC DISEASE.

DR. MASON presented the right os innominatum and sacrum, removed from the body of a man who had been a patient of Roosevelt Hospital, and who had been the subject of sacro-iliac disease. He was sixty-one years of age, and was admitted to the hospital January 20, 1875. About a year previous to this he had been in the institution suffering from elephantiasis of the penis, at which time the organ was removed by Dr. Weir. After leaving the hospital in August, 1875, he enjoyed perfect health for a month, when one night he was seized with a violent pain in the right hip. This extended along the outer and posterior portion of the thigh as far as the knee. The pain subsided somewhat in severity, and allowed him to follow his vocation as watchman.

On the following February he had another attack of most intense pain in the neighborhood of the hip and outer portion of the thigh. This pain was of a dull, aching character, and extended down to the knee-joint. The second attack confined him to his bed for a period of two weeks.

Just before his admission into the hospital he accidentally discovered a soft tumor on the anterior portion of the thigh, just below Poupart's ligament. This tumor had a vertical measurement of four and a half inches, and a horizontal measurement of four inches. It was regarded as a chronic abscess, and was aspirated February 4th. All this time the patient was able to walk about, and complained of nothing but a pain in the hip-joint. On the 5th of March Dr. Mason examined the patient very carefully, but did not succeed in finding any indication of disease in the articulation in question. On the 20th of August he began to complain of intense pain in the left hip-joint, which pain was so severe as to require hypodermic injections for its relief. About this time he had an attack of erysipelatous inflammation of the anterior portion of the thigh, after his recovery from which diarrhœa set in, which proved intractable, and he finally died of exhaustion, September 24th.

The autopsy revealed disease of the right sacro-iliac articulation. The ligaments of the part were destroyed, and the bones were extensively eroded.

The points of interest were: 1. The age of the patient, it being a disease almost entirely restricted to the young. 2. The ability to walk about during the progress of the disease. 3. The absence of any tumor or tilting of the pelvis to indicate the presence of the disease, and the final appearance of pus on the anterior portion of the thigh.

In connection with this case, Dr. Mason remarked that he had treated for this trouble a young man, aged twenty-three years, who was restored by absolute rest and counter-irritation by actual cautery.

DR. DELAFIELD remarked that he had seen four cases of the sort—all in adults—but in none was the diagnosis made before death. In all of them the anatomical characters were the same, viz.: erosion of the bone and destruction of the cartilage. There was no cheesy matter in or about the bone. The process did not resemble caries of the spine, nor destructive disease about the hip-joint, but seemed more like the suppuration which takes place in the vertebrae.

DR. MASON stated that Mr. Erichsen had never seen a case recover, while Mr. Hilton recorded two or three such; one particularly, in which a large abscess formed on the gluteal region, attended with much loss of tissue and adhesion of contiguous parts.

PERITYPHILITIS.

DR. WEIR presented a specimen, removed from a patient who had been the subject of an operation for perityphilitic abscess. The patient was a young man, aged nineteen years, who was first taken sick last May, with what appeared to be malarial fever, and which lasted three or four weeks. Following this attack he had diarrhœa, which although not severe was quite persistent. He was admitted into the hospital October 8, presenting a tumor in the right iliac fossa, which swelling he had noticed a week before. The tumor was easily recognized, involving the whole right iliac fossa, reaching up to the umbilicus, and losing itself over the region of the ascending colon. It was tender to the touch; temperature, $98\frac{1}{2}^{\circ}$ F. The diarrhœa presented no extraordinary symptoms. A rectal examination disclosed an indistinct tumor, high up towards the fossa. The patient having anasarctous extremities, and being a little below par, remained in the hospital until the 12th, when the tumor increasing in size, it was determined to use the aspirator, which was accordingly done. The needle was introduced about an inch and a half anterior to the anterior superior spinous process, and a drachm and a half of pus was obtained, when the instrument became choked and was withdrawn.

The following day the patient was placed under ether; the aspirator was again used, not only for the purpose of confirming the diagnosis, but as a guide to the knife. The incision was an inch and a half in length, and was carried across the centre of the needle through the abdominal walls. Then the aspirator was used as a guide, followed by the forefinger. The cavity of the abscess was opened and pus was evacuated. Although this pus did not present the characteristic odor of such discharged from an abscess directly or indirectly connected with the bowel, the possibility of its being of this nature was beyond a doubt. The next day fecal matter was discharged, and continued to discharge for a week afterwards. At the end of this time the discharge lost its fecal odor, became quite watery, and was then mixed with white particles looking like undigested milk. The probability of this discharge coming from the small intestine was thought of, but its possibility under existing circumstances hardly entertained.

The wound finally closed, and the patient went out on pass on the 29th. When he returned he felt badly. On examination, it was noticed that the tumor had increased in size. Unequivocal symptoms of peritonitis soon after showed themselves, and he died within a week afterwards.

At the autopsy there was found general peritonitis, the intestines on the right iliac fossa being firmly matted together. It was seen that the incision of the operation was opposite an opening (or rather the cicatrix of one), which had existed in a distended portion of the small intestine. This portion was in the jejunum, about twelve feet from its origin. The distention was due to a new growth, which so softened the intestinal walls as to insure ulceration at different points and perforation at the point previously referred to. The *caput coli*, although imprisoned in the mass, was perfectly healthy.

EXSECTION OF SHOULDER.

DR. WEIR also exhibited three and a half inches of the superior portion of the left humerus, which he had removed by exsection from a man forty-eight years of age, who had suffered for a considerable time with chronic suppurative disease of that joint. The operation was performed by the straight incision with the

view of saving the long tendon of the biceps. The glenoid cavity was so thoroughly involved as to necessitate its being gnawed off to a level with the ribs. The instrument, which did very effectual service in the latter step of the operation, was a cup-shaped gouge, which was exhibited to the Society. The operation was successful, and the patient was, at the time of reporting the case, doing well.

DR. MASON asked how far the elbow could be raised from the side in these cases.

DR. WEIR had never seen it exceed six or seven inches.

DR. MASON referred to a case operated upon by him, in which the arm could be swung up so that the hand could be placed upon the head, although the elbow by the ordinary efforts of the patient, could not be separated from the side farther than the usual distance of six or seven inches.

DR. WEIR remarked that this latter inability to raise the elbow was supposed by some to be due to a paralysis of the deltoid, due to injury of the circumflex nerve. This was to his mind hardly a sufficient explanation.

DR. MASON believed that it was due to the shortening of the distance between the origin and insertion of the said muscle, caused by the removal of the portion of bone.

DR. POST exhibited last phalanx and a portion of the second phalanx of the index finger, due to a neglected paronychia. He took occasion, in connection with specimen, to advocate the necessity of free and deep incisions as a preventive of the complication.

DR. POST lastly exhibited two small calculi, which he had removed by lithotripsy from a man aged fifty years; after which the Society went into executive session.

Correspondence.

INGROWING TOE-NAIL.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—So many methods have been proposed for the cure of ingrowing toe-nail, that I have some hesitation in saying anything upon the subject, the more so as I am not sure that the method I have adopted for some years past is at all novel, though as yet I have seen no mention of it in accessible authorities.

I have had constructed a small saw an inch and a half long, and something more than a sixteenth of an inch thick, with teeth filed square across, so as to give a chisel edge. With this I cut a longitudinal groove from the end to the matrix of the nail, and rather nearer the diseased side; another short cut is made across the convexity of the nail and as near as possible to its root, each cut extending nearly through its thickness. The segment on the diseased side is thus rendered quite movable. A slight nick is now made on each side of the nail, sufficient to lodge a bit of waxed silk, which is then carried around the two sections, and tied so as to draw them together, and allow one to slightly override the other. I then usually cut off a small portion of the nail next the ulcer, and elevate the edge by introducing beneath it a bit of oiled lint. The granulations are then touched with nitrate of silver, sprinkled with iodoform, and the entire toe enveloped in lint, soaked in carbolized oil. The ligature is left in

position long enough to allow the aggressive margin of the nail to assume a new direction of growth, and the ulcer to heal. While this procedure is not wholly painless, it is still less painful than any other method I have tried, and has been in every instance in my experience effectual, and permanent in its results.

J. L. Hicks, M.D.

FLUSHING, December 3, 1875.

NERVOUS DISORDERS FROM GENITAL IRRITATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Pertinent to the subject discussed by Dr. Jacobi, in his remarks upon nervous disorders arising from genital irritation, reported in your issue of December 4th, is the following case:

There are two reasons which dispose me to think a single case worthy of mention and record: the first is, that the subject is, as every one who has read Dr. Jacobi's remarks must feel, of great and insufficiently recognized importance in its bearing upon the development and nervous endowment of children; and the second, that the case illustrates, in a somewhat striking way, the peculiar views in regard to strictures "of extreme calibre," which Dr. Otis has the credit of having brought prominently before the profession. A gentleman, 35 years of age, a merchant, about a year since began to tell me of some trouble in his urethra. Some months before he had a clap which was fairly cured, and left no gleet. By and by he began to suffer from a thrilling pain, which he described as radiating from a point in the urethra, half an inch behind the corona glandis, outward to the left side of the dorsum of the penis. It was not an acute pain, but it was constant. Business must be very brisk or company very entertaining to make him forget it, or to interrupt a sexual crethism which it excited and maintained, to his great annoyance.

He was an unmarried man, and he did not like it that he could not see a woman without feeling an improper impulse toward her.

But his great trouble was at night. The pain teased him until he got to sleep, and when consciousness was suspended he had erections so urgent and continuous that his sleep was unrefreshing and his waking languid. In short, this matter was making a change in his whole life. He had been a keen and ambitious business man, but now he did not get to his store until noon, and was becoming a flabby erotomania.

Examination showed some redness about the meatus, but no discharge or tenderness on pressure. Examined by bougie, he complained of sensitiveness at the spot whence the pain radiated. By the endoscope nothing was determined. Successively steel sounds, 14, 16, 18 of the English scale, were passed into the bladder without trouble. Eighteen completely filled the meatus and even stretched it, though it passed onward without difficulty. The calibre of the passage was therefore at all points somewhat larger than at its orifice. This has been held to be conclusive evidence against the presence of stricture. Therefore at that time no larger instrument was tried. Regarding the case as a neurosis or possibly a neuroma of the submucous tissue, various expedients were employed. The most successful were pencils of butter of cacao, containing as much iodoform as might be mixed with it. One of these was passed down to the seat of irritation, at night a full dose of bromide of potassium given, and the genitals enveloped in a cloth wetted with ice-water. He said that this programme mitigated his priapism,

but obliged him to apologize to everybody for smelling so. But he kept it up for a good while, until the bromide seemed to produce a herpetic trouble of the skin. Then I suggested blistering under the track of the urethra. He approved, and wore several successive coats of cantharidal collodion, hiding his talent in a napkin for some weeks.

But all these ungracious methods appearing to be only of temporary use, I determined to stretch his urethra. With some force a bulbous bougie (31 French) was pushed through the meatus and fossa navicularis. It encountered resistance at the seat of the pain, but thence moved onward to the bulbo-membranous portion easily. In withdrawing, it was arrested at the same spot, and considerable blood followed its removal. Some days after, he returned to tell me that the pain and sexual irritation had been much relieved. The same process was repeatedly followed by the same result. About four days after each dilatation the irritation returned, and continued until the urethra was again stretched. This sufficiently showed that the whole train of symptoms depended upon a narrowing of the urethra, so slight as hardly to deserve the name of stricture. The case was typically an illustration of the views of Dr. Otis, who suggested, on hearing my account of it, division of the band. This I did thoroughly after freely incising the meatus, and passed bulb 39, of the French scale, down to the membranous portion. At last accounts, some six weeks after the operation, the man seemed to be entirely cured, but was passing at intervals of a week bulb No. 35, to prevent recontraction.

Dr. Jacobi raises the question, whether many of these cases which have been called reflex are not rather direct genital irritation, tending to an ascending neuritis or even myelitis. Such would seem to be the solution in the present instance.

W. M. CHAMBERLAIN.

68 W. 40TH STREET, Dec. 6th, 1875.

THE VENDING OF NOSTRUMS.

By THOS. D. McELHENIE, PH.G.

(Read before the N. Y. Alumni Association of Phila. Coll. of Phar., November 2.)

AN editorial in THE MEDICAL RECORD of Oct. 9th, entitled, "Shall it be a Profession or a Trade?" treats of pharmacy in its commercial phase, and the writer improves the opportunity to indulge in certain thrusts at pharmacists as "vendors of patent medicines." He diagnoses "an over-sensitiveness of the pocket nerve," and holds the following language: "Some of the semi-medical preparations thus sold have long since been proven by analysts to be possessed of positively deleterious, if not absolutely poisonous properties, and yet because the public, so called—a name which in this case is almost a synonym for a non-educated portion of the community—seek them, the druggist finds a convenient excuse for indulging in a traffic that is peculiarly profitable."

The insinuation of the remark quoted, to the effect that the pharmacist regards the sale of patent medicines as an indulgence, and is glad of the excuse of popular demand, behind which to screen himself, is most unkind and unjust to the respectable minority in the profession, who regard this feature as a nuisance, and would gladly aid in its discontinuance.

But as yet the fact remains that patent medicines of all sorts flood the market, and the public buy them, and buy them, too, of the apothecary, because by long usage his shop is the most natural place to look for

anything in the medical line. The nostrum-buying public would feel flattered at being told by their physicians that they comprised "the non-educated portion of the community." Such statements, however, would not be true. In fact, it is within the writer's knowledge that among the patrons of certain nostrums are numbered many of the best educated people, notably the clergy, who have an unaccountable propensity for endorsing nostrums, by which they incur a great responsibility. It may be well to consider some phases of the "over-sensitiveness of the pocket-nerve," which THE RECORD concedes as generally prevalent. It prompts the patient to buy patent medicines, because if they cure him it will probably be at less cost than regular treatment by a physician, and as he in most cases *imagines* they will cure, they often do.

The same affection prompts the pharmacist to sell patent medicines because the public demand them, there is little trouble attending their sale, and the profit helps eke out his oftentimes scanty income. It also prompts the physician to object to the sale of nostrums, as thereby his business is more or less affected, and consequently his bank account.

Admitting, then, the existence of the state of things described, and recognizing its injurious influence upon the public health, what is the remedy? In the opinion of the writer, it is not the measure proposed by THE RECORD, viz., a peremptory refusal on the part of the pharmacist to sell these nostrums. As the growth of the evil has been gradual, so its diminution must be accomplished by mild but constant and well-directed efforts on the part of *all* pharmacists. The medical profession is powerless in the matter, as any protest uttered by physicians would be ascribed to interested motives. To the pharmacist, then, we must look for alleviation of this nuisance; to this end it is important that he should realize his responsibility as the purveyor of medicines, and conjointly with the physician, as conservator of the public health. As a person of skilled judgment in such matters, his opinion is deferred to by his patrons, when he takes the trouble to express it. His duty, then, is never to recommend a patent medicine, keep no advertising matter setting forth their merits, allow no display of signs and show-cards, etc., in his shop, and if possible, as it often is, keep such nostrums out of sight of the public to supply only on customer's order, *provided* he cannot prevail upon him to consult a physician, or to try some remedy which he shall prescribe. A peremptory refusal to supply a patent medicine would only send the customer to the next drug store; or supposing there to be a unanimity among pharmacists on this point—a thing impossible—the proprietors of the tabooed preparations would establish agencies at other places of business, and thus the business of the apothecary would suffer without materially affecting the sale of the nostrums.

On the other hand, it is believed that a judicious and dignified pursuance of the course indicated above would secure to the pharmacist the respect of his patrons, thus inuring to his pecuniary advantage, while gradually doing away with the traffic in articles whose properties and composition are unknown alike to buyer and seller.

THE RECORD characterizes as a "half-way measure" the proposed issuing of an almanac by pharmacists, and says "it will be incomplete, unsatisfactory, and impracticable." Such advertisement will no doubt be appreciated by the publisher and editor, with whom the *Popular Health Almanac* is an accomplished fact.

In the writer's opinion, "half-way" measures are more likely to succeed in this matter than the violent

one of absolute refusal, and the substitution of the proposed almanac for the rubbish with which our counters are (by our leave) annually flooded, will go far toward lessening the demand for patent medicines.

In conclusion, it is suggested that two joint committees be appointed at the next annual meeting of the National Medical and Pharmaceutical Association, one of these being instructed to prepare a series of formulæ for household remedies, providing a suitable variety of each class to meet the varied wants of the family. These formulæ, brought to the notice of, and adopted by pharmacists, would measurably lessen the sale of nostrums among the large class who are unwilling to call a physician for every little ailment.

The duty of the second committee should be to obtain information relative to the laws governing the granting of patents on articles of a medicinal or cosmetic nature, and endeavor to secure by legislation greater stringency in these laws, and thus diminish the forces of the enemy.

From the Patent Office at Washington I have the following data, showing a gratifying declension in the issue of patents on "Medical Compounds." There have been granted in all about 650.

In 1872 there were issued.....	68
" 1873 " " "	39
" 1874 " " " about.....	30

As the number of items in the catalogue of the leading American dealer is probably several thousand, it is evident that a large majority of "patent medicines" are *not* patented after all.

FLATBUSH, L. I., Nov., 1875.

CHANGES IN THE PUBLIC SERVICE.

ARMY.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Dec. 12th to Dec. 18th, 1875.

WILLIAMS, J. W., Assistant Surgeon.—Leave of absence extended one month. S. O. 70, Headqrs. of the Army, Dec. 13, 1875.

YEOMANS, A. A., Assistant Surgeon.—Assigned to duty at Fort Richardson, Tex. S. O. 231, Dep't of Texas, Dec. 8, 1875.

ADAIR, G. W., Assistant Surgeon.—Assigned to duty at Fort McKavett, Tex. S. O. 233, Dep't of Texas, Dec. 10, 1875.

BEDAL, S. S., Assistant Surgeon.—Assigned to duty at Fort Concho, Tex. S. O. 233, e. s., Dep't of Texas.

WILSON, A. D., Assistant Surgeon.—Died at Camp McDowell, Arizona Territory, on Nov. 30, 1875.

The *British Medical and Surgical Journal* says that while three or four homœopathic practitioners were before the city committee recently with their roll of petitioners' names, to urge that a ward in the City Hospital be devoted to homœopathic treatment, and lamenting the absence of the petitioners themselves, their *first* and *chief* petitioner was at that very time convalescing under the care of a regular physician, having dismissed his homœopathic attendant some days previously.

Medical Items and News.

DR. A. JACOBI.—By an oversight of the printer, Dr. Jacobi did not have an opportunity of seeing the proof of his remarks on nervous affections in children. As a consequence, there are some inaccuracies of statement for which Dr. Jacobi is not accountable.

AMERICAN OTOLOGICAL SOCIETY.—At the last meeting of this Society, held in Newport, R. I., July 21, 1875, it was voted: That the Committee on an International Congress be empowered by this Society to issue a call for an International Otolological Congress, at such time and place as they shall see fit. In accordance with this vote, the Committee have called a Congress, to be held in New York City, on Friday, Sept. 15, 1876, at 10 o'clock A.M., the place of the meeting to be announced later. Members of the medical profession who take an active interest in aural surgery are cordially invited to be present and take part in the Congress.

Committee—D. B. St. J. Roosa, Clarence J. Blake, Herman Knapp, J. Orne Green.

THE NOUVEAU DICTIONNAIRE DE MÉDECINE ET DE CHIRURGIE PRATIQUES, published by Baillière & Son, of Paris, has reached the twentieth volume, and embraces Lacrymal Gland and Luxation.

PROFESSOR DITTEL, of Vienna, lately received from Baron Sina, a patient of the Professor, a present of a valuable casket containing twelve thousand gulden notes.

ERRATUM.—In the last issue of this journal, page 835, right-hand column, line 37, third word, read "magnesia" for "potassa."

NIGHT MEDICAL SERVICE IN ROME.—Dr. Lauchlan Aitken writes from Rome to the *British Medical Journal*, that a system of night medical service has for two years' time been in operation in that city, and that thus far it has been quite satisfactory. In Rome, when the night service was established, a pharmacy was selected in each of the five Rioni—the old *Regiones*—into which the city is divided for municipal purposes. These five pharmacies remain open all night, and are marked by a gas lamp of peculiar form, colored red, and distinctly marked, "Servizio Sanitoris Notturmo." To each of these are attached a certain number of physicians and surgeons who attend in rotation, receiving for each night of such attendance (from ten P.M. to six A.M.) the sum of seven francs, and any fees they may recover if called to patients who can afford to pay.

THE LATE ISAAC S. HUNT, OF PORT JERVIS, N. Y.—The Tri-States Medical Association, at its regular meeting Dec. 1, 1875, at Port Jervis, N. Y., passed the following on the death of Isaac S. Hunt, M.D., of Port Jervis:

Whereas, Since the last meeting of our Society death has invaded our Association, and has stricken down one of our fellow-members, Isaac S. Hunt, in the very prime of his manhood; therefore

Resolved, That in the death of our lamented brother this Society and the profession have suffered the loss of a worthy member, and one we had all learned to love and respect.

Resolved, That we unite in tendering to the family of our late brother and advocate the assurance of our deepest sympathy, not in the hope that we can lighten

the burden of their sorrow, but as an expression of our claim to share their grief as sincerely as we mourn his loss.

Resolved, That these resolutions be entered on the minutes of the Association, and that they be published in the local papers, and a copy sent to the family of our late brother, and also to the editors of the *Medical and Surgical Reporter* and *THE MEDICAL RECORD*, for publication in those journals.

Committee—B. G. McCabe, W. L. Apply, E. Crocker.

HARD ON THE PROFESSION.—A lay contemporary says that "America has one physician to every 800 inhabitants. That is, they begin on that basis, but after that there are not so many inhabitants."

THE OBSTETRICAL SOCIETY OF EDINBURGH are about to issue shortly a third volume of *Transactions*, embracing the three sessions, 1871-2, 1872-3, and 1873-4. It is now in the printer's hands, and will appear very soon.

ENGLISH MEDICAL ADDRESSES.—Dr. Parkes will give the Harveian Address at the Royal College of Physicians, London, next year; Dr. Habershon, the Croonian Lectures; Dr. Dickinson, the Lumleian Lectures; and Dr. Shephard, the Gulstonian Lectures. Dr. Sibson is soon to lecture before the Harveian Society, of London, on Bright's Disease and its Treatment.

DRINK AND DISEASE.—*The Lancet* of Nov. 13 gives some curious calculations which have been made of the proportional amount devoted by the workingmen of Birmingham to the support, respectively, of their public-houses and of their hospitals. The figures bear something like the ratio of thirty to one. £3,000 is contributed annually by them to the medical institutions of the town, and £900,000 is spent in drink. *The Lancet* further asks, "What proportion does the contribution of the workingmen bear to the total expenses of the hospitals?" which are for them and theirs only. On the other hand, what proportion of the work of these medical institutions is occasioned by the drink on which they spend so much? Commenting on the state of the case the writer says: "We remove every obstacle to as free a consumption of liquor as is consistent with the maintenance of equilibrium, and then, with a benevolent appropriateness, we provide hospitals in which the consequences of the drink can be recovered from, ameliorated, or assisted to an euthanasia." The corrective suggested for this state of affairs is "that the drink sold within a certain area should be so taxed as to defray the expenses of skilled treatment for those whom drink has prostrated and incapacitated for their work."

SMALL-POX is epidemic in Cincinnati, the greatest mortality being among children.

A SCHOOL OF MEDICINE FOR WOMEN is to be opened in Brussels in December.

WEEKLY BULLETIN OF THE MEETINGS OF MEDICAL SOCIETIES.

Monday, December 27.—Medical Society of the County of New York; Council of New York Academy of Medicine.

Tuesday, December 28.—Yorkville Medical Association.

Friday, December 31.—Medical Journal and Library Association.
